LECTURES
ON THE
PRINCIPLES AND PRACTICE OF
PHYSIC,

Delivered at King's College, London,

By DR. WATSON.

LECTURE XXVII.

Treatment of chronic hydrocephalus: internal remedies: mechanical expedients; bandages, tapping. Symptoms of spinal disease. Inflammatory conditions of the spinal marrow.

THE cure of chronic hydrocephalus may be attempted by internal remedies, or by external mechanical expedients, or by both.

Internal remedies.—The internal remedies by which most good appears to have been effected, and from which, therefore, most is to be hoped, are diuretics, purgatives, and above all, mercury, which is believed by many to have a special and powerful influence in promoting absorption. Conjointly with these, the abstraction of small quantities of blood from the head, by means of leeches, has been found beneficial.

Gölis advises that calomel should be given in half-grain doses, twice a day; or if that should purge too much, in doses containing only one-fourth of a grain. At the same time he would rub a scruple or two of mercurial ointment, mixed with ointment of juniper berries, upon the scalp, every night. He recommends that the head should be kept constantly covered also by a woollen cap. Infants require, he says, no other nutriment than good breast milk; while older patients should take a moderate quantity of meat. In mild weather they should be as much as possible in the open air. Under this plan of treatment he affirms that he has known the circumference of the head decrease by half

an inch or an inch in a period of six weeks or three months; and that perseverance in this method has frequently, in his experience, been followed by perfect recovery both of the mental and of the bodily powers. If no improvement should be perceptible in two months, he advises that diuretics should be given, *with* the former remedies; the acetate of potash, or squills, or both: that an issue should be made in the neck, or in each arm, and be kept discharging for several months. And he thinks that when convalescence has once begun, it is often much accelerated by minute doses of quina; the fourth of a grain, for example, thrice daily.

In a disease so unpromising as chronic hydrocephalus, we are warranted in trying any plan that has been found or supposed to be useful. An apothecary of considerable experience—now dead—once took the pains to write out and send me the particulars of two cases in which he had seen a peculiar mode of administering mercury successful. I will give you them nearly in his own words.

He had a lad, fourteen years old, whose name was Scott, under his care, with chronic hydrocephalus, in the year 1817. He had been ill two or three years. He was nearly blind, had very little use of his lower extremities, and could not walk across the room without support. He suffered violent pains in his head, and was unable to bear the least pressure on his scalp. His bowels were constipated, and his pulse “oppressed.” Cupping and blistering, and the blue pill, and drastic purgatives, and ordinary diuretics, tried in combination and succession, gave him temporary relief; but no permanent benefit was obtained. Dr. Gower then suggested a plan which he had himself found successful in such cases, and which had first been used by Dr. Carmichael Smyth, who had recorded ten cases of recovery under its adoption. Dr. Gower's plan was to rub down ten grains of crude mercury with about

a scruple of manna, and five grains of *fresh squills*: this was to be one dose; and it was to be repeated every eight hours.

My informant rubbed the quicksilver down with conserve of roses, and then added the fresh squills, making the whole into the consistence proper for pills, with liquorice powder. The patient took this dose three times a day, for nearly three weeks, without any ptyalism being produced. Its effects were great prostration of strength, and loss of flesh, with gradual relief of all the boy's sufferings. It operated profusely by the kidneys. The medicine was continued twice a day, and at length once, for another fortnight; when all the symptoms of the disease had disappeared. The boy was greatly emaciated; he was then ordered an ounce and a half of Griffiths' mixture thrice daily; and soon regained his health and strength, and got quite well. And he remained well eight years afterwards.

The success obtained in this case led to the pursuance of a similar course in that of the son of a well-known fishmonger in Old Bond Street. He was about twelve years old, and afflicted in nearly the same manner as Scott, except that the pain in the head was more acute, and caused violent screaming: *relief* had been repeatedly given for a time, by cupping. The physician in attendance was unwilling to try the plan, when it was proposed to him, but said that he would give what was equivalent—small doses of blue pill, with squills in powder. The result was salivation in a few days, without any amendment. In about three weeks, the effects of the mercury having subsided, and the patient then suffering extreme pain in the head, loss of sight, and want of power over the lower extremities, my informant was desired to adopt any measures he thought fitting. The medicine was given as in the former case, and with the same happy consequence; it acted, as before, without producing ptyalism, but with a great reduction of strength and flesh: health was restored by steel, after the symptoms of hydrocephalus had disappeared. This cure also was permanent.

I think you will give me credit for not being over fond of recommending what I may call *conundrums*, instead of well-tryed and approved means of cure; but I say that in such a complaint as chronic hydrocephalus, we have generally the opportunity of testing the virtues of many reputed remedies, one after another; and we are not to despise or neglect any measures that have been found beneficial, merely because they are out of the way, or because we cannot see in what manner they can excel the more common formulæ.

You will observe that these were cases in

which the disease came on some time after the sutures of the skull had closed.

Mechanical remedies.—The mechanical remedies of chronic hydrocephalus are two: and they have a totally opposite mode of action. By the one, the brain is compressed; by the other, it is lightened of its pressure: yet both of them have proved successful. What does this show? what, but a confirmation of the doctrine that there are different states of the encephalon, very dissimilar in their essential character, yet having some symptoms in common; and those the most likely of all to catch our attention. Such common symptoms resemble an algebraical symbol, which derives its value from the plus or minus sign prefixed. Surely it is of vital importance to study, and if we can to settle, the differences whereby these inverse conditions, requiring contrary remedies, may be discriminated.

Bandages.—*Bandaging* the head is one of these two expedients; *puncturing* it the other. Neither of them is practically applicable after the bones of the skull have united.

Bandages appear to have been suggested by the notion that the increase of the fluid within the head, and probably some of the symptoms too, might depend, more or less, upon the want of firmness and proper resistance in the outer containing parts; in the feeble and half solid skull. A certain amount of support and pressure seems requisite for the due exercise of the cerebral functions. Beyond this amount all increase of pressure is hurtful. The middle point of safety it may be hard to hit. It is certain that the easy yielding of the bony walls of the head, by reason of the membranous interspaces that exist in the early periods of life, proves oftentimes the safety of these patients. If the skull did not expand as the water gathered, morbid symptoms would ensue. Great nicety must therefore be required in the use of this remedy. While the head is palpably enlarging, compression by means of plasters or bandages would probably be mischievous. When the disease is stationary, and the unconnected bones of the skull are loose and fluctuating, and the child is pale and languid, much benefit may be expected from moderate and well-regulated support. The late Sir Gilbert Blane was the first, I believe, to suggest this mode of treatment; but its safety and efficacy have been more recently demonstrated by Mr. Barnard, of Bath, who has related several examples of complete success from the employment of bandages. In these cases the children were pale, bloated, and feeble, with flabby muscles: the bones of their heads were moveable and floating, and the functions of the brain more or less impaired. Mr. Barnard applies strips of adhesive plaster, about three quar-

ters of an inch wide, completely round the head from before backwards; covering the forehead from the eye-brows to the hair of the head, as low down on the sides as the ears will permit, and lapping over each other behind. Then, cross strips are carried from one side of the head to the other over the crown; and lastly, one long slip, reaching from the forehead, within half an inch of the root of the nose, over the vertex to the nape of the neck. In his first trial of this plan, but never afterwards, Mr. Barnard laid pieces of linen, wetted with cold water, over the plasters. The only internal medicine given was castor oil, to regulate the bowels. The effects, in all this gentleman's cases, were these: a gradual diminution of the size of the head; mitigation, and ultimate disappearance, of all head symptoms, such as strabismus, rolling of the eyes, starting of the muscles, and convulsions; and at the same time, increased tone of the muscular system, an improved appearance of the skin, and of the secretions from the bowels. These are striking results: they show that, in certain conditions of chronic hydrocephalus, a part of the danger arises from a lack of due support and confinement of the brain; and they prove that compression alone may be equal to the cure.

But in children who are not of this pale and feeble habit, and in whom ossification of the skull goes on, the period when the walls cease to yield is the period of danger. The water continuing to accumulate, inordinate pressure begins to take place. To such heads the application of bandages or plasters must, if nothing else be done, be insufficient or unsafe. The brain-case being no longer capable of expansion, there remains to be attempted a reduction of the quantity of the liquid which it contains.

Tapping the head.—Now any considerable diminution of the accumulated fluid, through the agency of mere absorption, is scarcely to be expected; even although we endeavour to aid that process by applying leeches and cold to the head, and by purgatives, or diuretics, or diaphoretics. Some mode, more certain and effectual, of emptying the distended cavity, has therefore been earnestly sought after; and the second mechanical expedient of which I have spoken offers a very sure method of attaining this object. He must have been a bold physician who first proposed to decant the water from the brain, by means of a perforation, made with a trocar, through the membrane of the fontanelle, the membranes of the brain, and even the expanded cerebral substance itself. But the success of the project has amply vindicated his happy audacity. It is not a very new suggestion, but it has received particular attention in this country of late years: and though tapping the brain

in chronic hydrocephalus has been denounced as useless and cruel by some high continental authorities, by Göllis and Richter especially, it furnishes one of the best of the few chances of safety to the patient. Of course I mean ultimate safety, for the operation itself is attended with the present risk of accelerating the patient's death. Other means, however, failing, we are justified in advising that hazard. We have to consider that by performing the operation we incur the danger of abbreviating the existence of a being, whose life, without it, could scarcely be long continued, or capable of enjoyment: but then we afford *some* chance of a perfect cure. A speedy death, or an uncertain life of mental and bodily imbecility, or complete restoration: these are the three events to be looked at. Of the three, the second is, in my judgment, incomparably the worst; and if the case were my own, if I had to decide the painful question in reference to one of my own children, I would accept the alternative of probable speedy death on the one hand; possible complete recovery on the other.

To say the truth, the *immediate* danger is not so very great as you might suppose; provided that the operation be skilfully and cautiously performed, and only a moderate quantity of water drawn off at a time. That even a very rough operation is not necessarily fatal we learn from a singular case related by Mr. Greatwood. A child, 15 months old, afflicted with chronic hydrocephalus, fell down, and struck the back part of its head against a nail, which penetrated the skull. Above three pints of water gradually flowed out at the orifice thus made, and the child was cured.

I will mention a few instances in which tapping the brain has been performed; for I know no better mode of shewing you the manner in which the operation should be done, the cautions to be attended to in doing it, and what kind of success it has had.

There is an account of the performance of this operation by Lecat, in the *Philosophical Transactions* for the year 1751. This date is subsequent to the period when the Rev. Mr. Stevens suggested the propriety of trepanning Dean Swift's cranium. In 1778, Dr. Remmett, of Plymouth, punctured the head of a hydrocephalic child on five several occasions, with a lancet, and took away, in all, no less than 80 ounces of fluid; five pints, as pints were measured in that day. The child died 17 days after the last tapping. A very interesting case of the same kind is related by Dr. Vose, of Liverpool. His patient was an infant seven months old. Its head was more than twice the ordinary size. Three operations were performed; the first with a couching needle. Upwards of three ounces were on that occasion evacuated;

and it was estimated that about the same quantity dribbled away afterwards. The child thereupon became very weak, but was presently revived by some cordial medicine. About six weeks afterwards, the liquid having collected again, an opening was made with a bistoury, and 8 ounces were removed; and 9 days after that 12 ounces more, without any bad consequences. The head diminished in size, the patient got apparently well, and the case was published as a successful one. Unfortunately, however, the complaint afterwards returned, and the child died of it.

Mr. Lizars, of Edinburgh, operated upon a little patient of his twenty times in the course of three months; using a small trocar. Upon the escape of the water, squinting, and dilatation of the pupils, which previously existed, ceased immediately. The child recovered. Another very striking and instructive instance is recorded by Mr. Russell, of Edinburgh. The patient was an infant three months old, with an enormous head: twenty-three inches in circumference, and fifteen inches and a half from one ear to the other. The child was affected with strabismus, and a perpetual rolling of the eyes. The usual routine measures, compression among the rest, had been employed without any success. By four operations performed at intervals of about ten days, the size of the head was considerably diminished: but, the fluid continuing to collect, calomel was given in small and frequent doses, and the gums became sore, and the child got well. At eight months old the dimensions of the head were less, by four inches in circumference, and by two inches and a half across the vertex, than they had been previously to the first tapping; and the sutures had entirely closed.

But Dr. Conquest, of Finsbury Square, has, more than any other person, given authority to these operations. In a paper published in the *MEDICAL GAZETTE* in March 1838, he tells us that he had then tapped the heads of 19 children for this complaint, and in 10 of the 19 cases the children survived. He introduces a small trocar through the coronal suture below the anterior fontanelle, and cautiously makes pressure upon the head afterwards by means of strips of adhesive plaster; and he closes the wound in the integuments carefully after each time of puncturing. The greatest quantity of liquid withdrawn by him, at any one time, has been twenty ounces and a half; and the greatest number of operations on any one child has been five, performed at intervals of from two to six weeks. The largest total quantity of water removed was 57 or 58 ounces, by five successive tapplings.

This expedient, therefore, though doubtless hazardous, is really a valuable one.

The rules relating to its performance may briefly be summed up. The operation should scarcely be had recourse to until other means have failed. The trocar should be small, and it should be introduced perpendicularly to the surface, at the edge of the anterior fontanelle; so as to be as much as possible out of the way of the longitudinal sinus, and of the great veins that empty themselves therein. The fluid should be allowed to issue very slowly; and a part only of it should be evacuated at once. The instant that the pulse becomes weak, or the dilated papil contracts, or the expression of the child's countenance manifestly alters, the canula should be withdrawn, and the aperture in the skull closed. Gentle compression should be carefully made, to compensate, in some degree at least, the pressure that has been removed with the fluid. Should the infant become pale and faint, it must be placed in the horizontal posture; and a few drops of sal volatile, or of brandy, mixed with water, should be given. Sometimes slight inflammatory action comes on in the course of a day or two after the tapping. When this happens, we must apply cold lotions, and leeches, and use the other remedies which I mentioned before, as proper to subdue such inflammation.

I once got a surgeon to perform the operation upon the infant of a poor woman, after I had tried in vain all the other measures that I have spoken of. To our horror, when the trocar was withdrawn from the canula, instead of clear serosity, a fine stream of purple blood spouted forth. The opening was at a considerable distance from the longitudinal sinus; but the trocar was not so delicate as it might have been, and I presume that one of the larger superficial veins had been pierced. I do not think, either, that the instrument was introduced in a sufficiently perpendicular direction. Of course the risk of hitting a vein is increased when the trocar is carried obliquely inwards: and a larger portion of the cerebral mass is also wounded. We naturally thought it was all over with the child, which presently became deadly pale and faint. A verdict of *infanticide by misadventure* stared us in the face. But under the use of stimulants the infant revived again; no hæmorrhage went on internally, as we apprehended it would; but the child, after a day or two, was very much the better for the loss of blood. This amendment, however, did not last; and the mother, who had been terrified by the immediate consequences of the operation, feared to come near me, lest I should wish to have it repeated: and at length our patient died. I had no opportunity of examining the condition of the head internally, which I had much desired to do.

On one subsequent occasion I have witnessed the operation. The subject of it was an infant about eight months old. Four months after its birth, its head was observed to grow inordinately large. At the time of the operation the fontanelles were exceedingly tense; the child screamed frequently, occasionally vomited, and was slightly convulsed; the features were pinched, and the eyeballs distorted downwards; but the pupils were not dilated. Four ounces of transparent liquid were let out by puncturing the anterior fontanelle. A few hours afterwards the child was tranquil, and much improved in aspect; the distortion of the eyeballs had disappeared. Three ounces more were taken away the next day. For two days thereafter all the symptoms appeared to be mitigated; but the skull was flaccid; yielding, like a broken egg, to the gentlest pressure. On the evening of the fourth day after the first tapping, the respiration became hurried, the child grew dull, and, before midnight, expired. In this case it appeared to me that the chance of success was balked by the want of external support subsequently to the tapping.

You will not expect me to draw any comparison between the merits of compression and of paracentesis, as substantive remedies. They are opposite measures, and adapted to different and opposite conditions of the brain. The one supplies defect of pressure; the other relieves its excess. To hold the balance even requires much care, a steady and gentle hand, an accurate judgment, and incessant vigilance. Either expedient may suffice, alone. Both may be (and have been) profitably employed in the same case, in succession, according to its varying circumstances. If the walls of the head be tight and firm, the trocar should precede the bandage; if lax and moveable, compression should be cautiously tried, and followed, if need be, by the puncture.

I have now done with the *inflammatory* affections of the *brain*: in conjunction with which I have also considered some other morbid conditions, that are either connected with inflammation of the contents of the cranium, or resemble it in some of their phenomena. Thus, I have spoken of *delirium tremens*, which is apt to be mistaken for inflammation of the brain: of *softening from disease of the cerebral arteries*, which is liable to be confounded with inflammatory softening: of *tumors* of different kinds, which tend to produce inflammation, or symptoms like those belonging to inflammation: and of *chronic hydrocephalus*, which sometimes is the sequel, sometimes the precursor, of acute hydrocephalus; and has other points of analogy with that disease, the encephalitis of children.

Spinal cord.—Before I take up the subject of apoplexy, and of cerebral hæmorrhage, I wish to direct your attention to the inflammatory conditions of the spinal cord.

The whole pathology of this portion of the nervous system is extremely interesting; but it has not yet been so thoroughly made out as to enable any one to give a very systematic or satisfactory account of it. In addition to those numerous difficulties with which I shewed you in a former lecture that the entire subject of the diseases of the nervous apparatus is beset, there is this further obstacle to our studying diligently the disorders of the spinal marrow—that much labour and expense of time are required for exposing the interior of the vertebral canal; which is, therefore, too often neglected in examining the dead body.

There are certain points in the anatomy and physiology of the spinal cord which it is necessary that you should bear in mind, if you would have any clear notions even of what has been learned in respect to its pathology.

1. In the first place the spinal cord (including the medulla oblongata) is the seat and centre of that remarkable property, the reflex function; by which so many of the automatic movements of the body are governed.

2. In order that we may feel, or be conscious of, what occurs in any part of the trunk or limbs, and in order that our will to move any such part should be successful and obeyed, it is necessary that there should be a continuity of nervous matter between the part in question and the brain. If the cord be cut across at any point, or so crushed as to be thoroughly disorganized at that point, a complete abolition of sensation and of *voluntary* motion ensues in all those parts of the body that receive their sentient and motor nerves from that portion of the cord which lies beyond the place of the injury, reckoning from the brain; and what is true in this respect of the mechanical division of the cord, is equally true of such disease as pervades and spoils the nervous matter composing it.

Now it follows from this, that the effect of disorganizing forms of disease—as well as the effects of injury—vary greatly according to the part of the cord they occupy.

Thus any injury or disease situated in the spinal marrow, and pervading its whole thickness, where it is contained within the upper cervical vertebrae, is inevitably fatal at once; producing suffocation by paralyzing those muscles by the play of which the motions of respiration are performed. You know that the intercostal muscles and the diaphragm have at all times the main share in carrying on the mechanical actions of respiration; and probably they execute the

whole action in every case of ordinary breathing. Now the intercostal muscles are supplied with nerves from the spinal cord all along the dorsal vertebræ; and the diaphragm is principally supplied by the phrenic nerves, which are chiefly derived from the third and fourth cervical nerves. These muscles obey the will; but they act also independently of the will. The pneumogastric nerve, with respect to them, is an excitomotor nerve, and calls into play a reflex power which is transmitted from the medulla oblongata. Hence any profound injury of the spinal cord, above the origin of the phrenic nerves, stops both the voluntary and the involuntary movements of the respiratory muscles, and the individual perishes by apnoea in as strict a sense as though the access of air to the lungs had been suddenly prevented by a ligature drawn tightly round his wind-pipe.

Again, when a segment of the cord, however small, is disorganized in its cervical part, between the origin of the phrenic and the origin of the upper intercostal nerves, the breathing is not instantly suspended; but is performed entirely by means of the diaphragm, the intercostal muscles having no share in it. The ribs cease to rise and fall; and the abdomen is alternately protruded, and sinks back again. In each case I suppose the disease of the cord to be such as suffices to paralyze the parts supplied with nerves from it, below the seat of the disease. If disease of this kind occur below the giving out of the intercostal nerves, the breathing is not affected; we have *paraplegia* only, palsy and loss of feeling in the lower extremities, and, perhaps, in the hips, or even higher. Now a person in this condition *may* live a long time. When the disease is situated between the origin of the intercostal nerves and the origin of the phrenic, he may live a few days, but he seldom lives a week, and he never survives a month: and when the disease is higher still, in the very upper part of the cord, above the origin of the cervical nerves, he perishes outright. The *kind* and *degree* of disease, therefore, being the same, the character of the symptoms, and the amount of danger, differ remarkably according to the *seat* of the disease.

3. Although sense and voluntary motion cease upon the disruption of the communication with the brain, the excitomotor functions of the separated portion of the cord are not necessarily suspended. On the contrary, they seem to acquire increased activity. The automatic power is apt to run riot, as it were, when the controlling influence of the sensorium is lost. Each of you has probably seen the limbs of a recently decapitated frog thrown into violent action by the stimulus of galvanism. I have witnessed the same thing in the human

body after death by hanging. What is still more curious, you may have unequivocal manifestations of similar phenomena in the *living* body. I have lately been informed, by Dr. William Budd, of a case in which a man was afflicted with paraplegia, in consequence of disease of the vertebral column. He was totally deprived of the power of moving his lower extremities. Sensation in them was almost, yet not entirely extinct. A sharp pinch, or the prick of a pin, he could feel; but slight friction he was quite unconscious of: yet (as he himself said) his limbs were not; for when the inner edge of the foot was brushed or tickled by the hand of another person, the corresponding leg, over which he had no voluntary control, would start up, and be briskly convulsed. The same thing took place, in both limbs, whenever he passed his urine or feces; so that he was obliged to have an apparatus of straps and ligatures to keep the legs down on such occasions. I have seen something like this myself*.

Separate and different filaments of the spinal cord connect themselves with, or help to form, different nerves which emerge from the crano-spinal axis. A knowledge of this fact enables us to understand how it happens (as it sometimes does happen) that the upper extremities are deprived* of sensibility, or of voluntary motion, or of both, by disease of the cord, while the same functions remain perfect in the lower and more distant limbs. Here the disease must have spared those strands or filaments of the cord which pass down to connect themselves with the nerves given off at the lower part of the spine; while it has affected those strands or filaments only which belong to certain nerves from the upper part.

4. You must bear in mind also the important discovery of Sir C. Bell, that the two roots by which each spinal nerve arises have distinct and different functions; the anterior roots being composed of motor fibrils, the posterior of sensiferous.

It is not so clear, although that opinion is, I believe, a prevalent one, that the anterior *columns* of the spinal cord are subservient to the purposes of motion, and the posterior to the faculty of sensation. This has been inferred, too hastily perhaps, from the ascertained endowments of the anterior and posterior *roots* of the *nerves*; and cases are cited which appear to favour such a notion: but then other cases go completely to contradict it. Thus Mr. Stanley has recently published an account of a patient who died in St. Bartholomew's Hospital. For some time before his death he had been completely unable to

* This very interesting case has since been published, in detail, with several others resembling it, in the 22d volume of the *Medico-Chirurgical Transactions*.

move his lower limbs, throughout their entire extent; while there was no discoverable impairment of sensation in any part of either limb. The spinal cord was the only part found diseased; and the disease was strictly limited to its posterior half or column. This portion of the cord, in its whole length, from the pons to its lower end, was of a dark brown colour, and extremely soft and tenacious. The anterior half, in its entire length, exhibited its natural whiteness and firm consistence. The roots of the spinal nerves were unaltered.

It was remarkable, and illustrative of the difficulty of these subjects, that with the change of structure which the cervical portion of the cord had undergone in this instance, there was no impairment either of motion or sensation in the upper limbs.

5. We must not forget that the brain, and the spinal cord, which are distinct from, but yet continuous with each other, sympathize largely and mutually under disease. This circumstance throws an additional obscurity over the study of their morbid conditions. It is one, however, which we cannot avoid, but which we must estimate and allow for, in our observation of diseases, as we best may.

6. There are a few remarks made by Dr. Abercrombie in relation to some of the anatomical dispositions of the cord and its investing membranes, which may help us to comprehend better some of their morbid contingencies. Thus, with respect to the dura mater of the cord, it is practically of importance to recollect "that it adheres very slightly to the canal of the vertebrae by a very loose cellular texture; and that it adheres very intimately to the margin of the foramen magnum. In this manner a cavity is produced betwixt the membrane and the inner surface of the spinal canal (external, *i. e.* to the membrane), which cavity may be the seat of effusion, and which has no communication with the cavity of the cranium. On the other hand, the space between the dura mater and the pia mater (or membrane immediately covering the cord), communicates freely with the cavity of the cranium; so that fluid may pass easily from one to the other, according to the position of the body."

Inflammation of the Spinal Cord.—I shall pursue the same order, in speaking of the inflammatory affections of the spinal cord, as I followed in respect to the analogous conditions of the encephalon. And, first, let us inquire what has been noticed of inflammation of the *membranes* of the cord. They may undergo inflammation, independently of the substance of the cord, and independently of the brain: but this is

not very common. Usually, when we have meningitis of the cord, we have the same disease also within the cranium: usually also, with meningitis of the cord, we have more or less inflammation of the nervous matter composing it. The commonest symptoms of inflammation of the meninges of the cord (for I do not pretend to speak of the several membranes separately) appear to be pains, often intense, extending along the spine, and stretching into the limbs, and aggravated usually by motion, and simulating therefore rheumatic pains: rigidity or tetanic contraction, and sometimes violent spasms of the muscles of the back and neck, amounting in some instances to perfect opisthotonos: a similar affection of other muscles also, as those of the upper or lower extremities: a sense of constriction in various parts, in the neck, back, and abdomen, as if those parts were girt by a tight string: a feeling of suffocation: retention of urine: obstinate constipation: and with these symptoms, rigors often.

You are not to expect all the symptoms which I have been enumerating in every case: they will vary according to the seat and extent of the inflammation. We need not wonder at the spasmodic symptoms, when we recollect that the nerves which issue from the body of the cord receive a covering from its pia-mater. The pain felt along the course of the spine itself is said to be aggravated by percussion of the spine, but not by simple pressure; and this seems very likely.

I know of no way in which I can so well hope to awaken an interest in you about these diseases, or to offer you instruction respecting them, as by instances. The following I take, abridging it somewhat, from Dr. Abercrombie. A man, twenty-six years old, had for several years been subject to suppuration of the left ear; suffering occasional attacks of pain on that side of the head, which were followed by a more copious discharge from the ear. In the first week of April he became ill, with pain of the forehead and occiput, disturbed sleep, and loss of appetite; but no fever. At the end of the week he complained of pain extending along the neck. This pain gradually passed downwards in the course of the spine, and deserted the head; and at last, after many days, it fixed itself with intense severity at the lower part of the spine; shooting thence round the body towards the crests of the ilia. He became affected also with great uneasiness over the whole of the abdomen, and with great pain and difficulty in passing his urine. About the end of the second week in April his sufferings had become extreme. He could not lie in bed for five minutes at a time, but was generally walking about the

house in a state of great agitation, grasping the lower part of his back with both his hands, and gnashing his teeth with the intensity of the pain. He had no interval of ease, and was sometimes incoherent and unmanageable. On the 16th he went to take a warm bath, walking down three stairs, and into an adjoining street, with little assistance. His speech afterwards became somewhat affected: there were convulsive twitches of his face, and difficulty of swallowing. Some transient squinting also was observed. The pulse was now very frequent. On the 18th, while sitting in a chair, he suddenly threw his head backwards with great violence, and immediately fell into a state of coma, in which he remained for two hours, when he died. During the whole disease there had been no paralysis, except the slight affection of his speech; no difficulty of breathing; no vomiting; and no convulsion except the twitching of his face the day before his death. The pulse was small and irregular. The bowels were easily kept open, but the pain in his back was much increased by going to stool. Two days before his death he had several attacks of shivering; and much purulent matter was discharged from his left ear during his illness.

Upon a very careful examination of his body, every part of the brain was found to be in the most healthy state. Some gelatinous deposition was found under the *medulla oblongata*; and purulent matter flowed, in considerable quantity, out of the spinal canal. The spine being entirely laid open, the cord was found covered with a coating of purulent matter, which lay betwixt it and its membranes. The matter was most abundant at three places; at the upper part, near the foramen magnum—about the middle of the dorsal region—and at the top of the sacrum: but it was also distributed over the other parts with much uniformity. The substance of the cord was soft, and separated into filaments in some places. All the other viscera were healthy.

You may find several interesting examples of this form of disease in *Ollivier's Treatise on the Spinal Marrow*. The prominent symptom was generally *pain*, referred to some part of the spine, and *increased by motion*; and what is curious, sometimes little complained of except upon motion. In general, also, it extended along some of the limbs, and was accompanied by muscular rigidity, or tetanic spasms. Palsy occurred in one case: but this seemed to have been owing to *softening* of the cord itself. Constantly there was increased sensibility; a circumstance which Ollivier thinks calculated to distinguish inflammation of the membranes from inflammation of the substance of the

cord, which is usually attended with *diminished* sensibility. In the case that I have quoted from Dr. Abercrombie, the intense pain underwent no remission or abatement. In one of Ollivier's examples, there was, at the commencement of the disease, a striking intermittence of the pain; it came on with intense severity at ten at night, and lasted till three in the morning.

The causes of spinal meningitis are not always to be discovered. It sometimes extends from within the cranium. It may be excited by external violence to the spine, of which a good specimen has been recorded by Sir Charles Bell:—A waggoner sitting on the shafts of his cart, was thrown off by a sudden jerk, and pitched upon the back of his neck and shoulders. He was taken to the Middlesex Hospital, where he lay for a week, without complaining of any thing except stiffness of the back part of the neck. He could move all his limbs with freedom. On the eighth day after his admission he was seized with general convulsions and locked jaw. After a few hours he was affected with a singular convulsive motion of the jaw, which continued in violent and incessant movement for about five minutes. This was followed by maniacal delirium. He then sunk into a state resembling typhus fever; and after four days was found to be palsied and insensible in his lower extremities. The day before his death he recovered sensation in his legs.

On dissection, a great quantity of purulent matter was found within the spinal canal. It appeared to have formed about the last cervical and the first dorsal vertebræ, and to have dropped down, by its own gravity, to the lower part of the canal; where it produced palsy and anæsthesia of the inferior limbs by the pressure it occasioned.

Inflammation of the *substance* of the spinal cord leads to the same changes in its texture which have been already spoken of as being often the results, in the brain, of inflammation of the *cerebral* matter. Softening—induration—suppuration. I need not, therefore, again describe the physical characters of these alterations.

The symptoms which flow from inflammation of the nervous pulp of which the spinal marrow is composed, are by no means uniform; nor can we expect that they should be so, when we recollect what has been already stated of the different effects that must ensue according as different parts of the cord happen to be implicated. The phenomena will vary likewise, according as the inflammation is acute or chronic. If we bear in mind how many parts of the body depend for their power of motion, and for

their sensibility, upon the integrity of the spinal cord, we shall not be surprised at the diversity and multiplicity of the symptoms that flow from disease of the cord. We shall expect to find, and we actually do find, some such an arrangement of those symptoms as the following. When the upper portion of the spinal marrow is inflamed, or partly disorganized, we look for convulsive affections of the head and face; inarticulate speech, loss of voice, trismus, difficult deglutition: as we go somewhat lower we should anticipate difficulty of breathing, irregular action of the heart, constriction of the chest: and proceeding lower still, vomiting, pain of the belly, sensation of a cord tied round the abdomen, dysuria, retention of urine, incontinence of urine, constipation, tenesmus, involuntary stools. And with respect to the voluntary muscles corresponding to these parts of the spinal marrow, convulsions, or palsy; or palsy succeeding to convulsions.

I must again have recourse to examples, to put you more fully than any attempted abstract picture could put you in possession of such forms of inflammation of the cord as you may expect to meet with in practice.

A man, 56 years old, was exposed to severe cold, while travelling on the outside of a coach. After this he was attacked with pain in the right arm and leg, most severe about the shoulder, but affecting the whole side, and he had also considerable headache. He soon perceived some loss of power in the affected limbs; and the progress of this was very curious. It began at the upper part of the arm, and extended downwards so gradually, that he was able to write distinctly, after he had lost the power of raising the arm, or bending the elbow. Then the leg became affected in the same gradual manner, and after ten or twelve days from the commencement of the disease, the whole leg and arm had become completely paralytic. Some pain continued in the parts, and it was occasionally severe, especially in the leg. Repeated blood-letting, and purgatives, and blistering, were employed. His mind remained quite entire. His pulse was 84, and rather weak. After some time the left arm became paralytic, rather suddenly; but it was not so completely motionless as the limb on the right side: the left leg was not at all affected. Slight delirium occurred, but passed off again. At the end of two months, after the exposure to cold, he again became delirious, and his pulse got feebler and rapid: he then fell into a state of stupor, muttering incoherently, but answering questions distinctly when he was roused. He lost his speech a few hours before death. For the last eight or ten days there had been considerable sloughing of the sacrum.

The brain was found to be healthy throughout. Much bloody fluid was discharged from the spinal canal into the cavity of the cranium before the spine was laid open. On displaying the spinal cavity itself, the cord was found in a state of complete softening, from the second to the last cervical vertebra. The portions above and below that part were quite healthy (*Abercrombie*).

Comparing this case with the one I detailed of meningitis, we find that pain was present in both, but more severely so in the case of inflammation of the membranes: we find, also, that *stiffness and spasm of the muscles* marked the meningitis; *palsy* the inflammation of the substance of the spinal cord. In neither of them were the intellectual functions disturbed till towards the last. I believe that the characters now pointed out belong to these forms of disease respectively.

I shall take, from the same store-house, one more case, in which both the membranes and the cord were simultaneously inflamed; and which, therefore, was analogous to encephalitis. And I quote it the rather because it possesses one or two points of peculiar interest. A young man, of unhealthy constitution, 18 years old, had suffered for some time from ulcers in various parts of the body, accompanied by exfoliations of bone from the leg, thigh, and sacrum. For several months before his fatal attack he had a sore on his head, as big as a shilling, with caries of the bone beneath it. At length he began to complain of pain in the loins, without fever. On the 2d of October this pain had increased; it was chiefly seated among the lower dorsal vertebrae, and extended downwards in the course of the ureter, with a frequent desire to pass urine. Then the pain descended lower, into the sacrum, and the symptoms referable to the bladder ceased. But soon afterwards pain in the belly came on, and numbness of the inner side of the thighs, and retention of urine; and in two days after this there was *perfect palsy* of both thighs and legs, *without loss of feeling*; retention of urine, and involuntary stools. He had still some pain in the lower part of the dorsal region. He died at length, on the 14th of October, having continued quite sensible till about six hours before. There had not been the smallest approach to a renewal of power of the lower extremities, but their sensibility remained. There was *palsy*, but no *anesthesia*.

All was quite sound in the brain, except some old thickening of the dura mater in the neighbourhood of the diseased bone. In opening the spinal canal, some purulent matter flowed out, during the sawing, from about the middle of the dorsal region; and one of the vertebrae at that place was found

carious. There was an extensive deposit of flocculent matter, having a purulent appearance, upon the outside of the membranes of the cord. Bloody sanious fluid was discharged from beneath its dura mater, and its pia mater was highly vascular. The substance of the cord was found most extensively disorganized along nearly the whole extent of the dorsal portion. The *anterior columns* of this part were completely broken down into a soft diffuent pulp; on the *posterior part* the cord was *more entire*. When the whole cord was taken out, and suspended, it hung together by the posterior columns of the dorsal portion, while the anterior part of it fell off entirely, in a soft half fluid state. The parts above and below the diseased portion were quite firm and healthy.

The complete palsy in this instance, going along with the destruction of the *anterior columns*; and the persistence of the sensibility, the *posterior columns* being comparatively entire; invest the case with a remarkable degree of interest. We might infer from it that the anterior half of the cord is the channel through which the power to move the limbs is transmitted, while their sensations are carried along its posterior half; but we are checked from so concluding, by such cases as the one recorded by Mr. Stanley. These apparent inconsistencies may puzzle, but they ought not to discourage you. That time, and our advancing science, will at length explain and reconcile them, I cannot doubt. Meanwhile they teach a lesson which many practitioners much need—viz. that it is unphilosophical and unsafe to draw general conclusions from single cases of disease.

We are much instructed in regard to the effects of inflammation, or any other cause of disorganization, *confined to a limited portion of the cord*, by observing what takes place in those injuries in which the bones of the vertebral column are broken, or displaced. Of course I do not dwell upon these accidents, for they belong to surgery; but I have seen a good many of them, and watched them with much interest. The symptoms are much more uniform than when inflammation occurs within the vertebral canal, independently of external injury; simply because the injury to the cord is more definite and local. But such cases are very valuable objects of study to the physician. I remember several that occurred when I was a dresser in St. Bartholomew's hospital; and I will state very briefly the particulars of one, as an exemplar. In the year 1820, a man was brought there who had been thrown out of a tilt cart, in consequence of a dray running foul of it. He had pitched upon his head, which shewed however no

trace of injury. He became powerless, both in the upper and lower extremities, immediately on the receipt of the injury. His stools passed from him without his being aware of it, and it was necessary to use the catheter to empty his bladder. He breathed entirely by the diaphragm—that is, his thorax was motionless, and his abdomen rose and fell with every alternate act of inspiration and expiration. These symptoms are perfectly distinctive of injury to the cord between the origins of the phrenic and intercostal nerves. He suffered pain about the middle part of the neck behind. He went on exceedingly well for four or five days, and then the nurse very foolishly acceded to his request to be turned on his side, which caused his death in a very few minutes. This is not the only instance, by the way, in which life has been suddenly extinguished by similar imprudence. The lesson may be useful. There was another patient in the same hospital, who had fractured the spinal column about the cervical vertebrae. Among other remedial measures, the surgeon had directed that his head should be shaved. The barber had performed half his task, and was turning, with his hands, the unfortunate man's head into a more convenient position for completing it, when he suddenly expired. The twist was fatal to him.

On the examination of the body of the patient whose case I was mentioning, a very remarkable state of the spinal column was found. The fifth and sixth cervical vertebrae were dislocated from each other *without any fracture*: a thing which has sometimes been pronounced impossible. The articular processes were fairly separated; and the vertebrae were also forced asunder, by the detachment of one of them from the intervertebral substance. The nervous matter of the cord opposite the point of dislocation was quite soft.

There is one very common and distressing consequence of such disease of the spinal marrow as produces paraplegia, not particularly noted in any of the cases which I have related, but always to be looked for. The muscles, by means of which the bladder empties itself, are apt to participate in the palsy; and then the bladder empties itself no longer. The urine accumulates in it, and distends it, and the ureter even becomes distended; and in this way not only the present but the prospective danger is increased. For the foundation of future disease in the kidneys is often thus laid, even when such distension of the bladder by its retained contents occurs independently of any disease of the spine; as it may do from stricture; from enlargement of the prostate; or even from the voluntary reten-

tion of the urine beyond a certain period, through feelings of delicacy. You are to look out, I say, for this distension of the bladder, and relieve or prevent it by the introduction of a catheter through the urethra. You must not be deceived by being told that the patient passes plenty of water; that it even runs from him. Incontinence of urine is, in fact, in these cases, though it may sound paradoxical, a sign of retention of urine. The urine dribbles away because the bladder admits of no further distension; it overflows, and runs out at the natural orifice, but the bladder remains constantly full and stretched. You must make an examination, therefore, of the hypogastric region with your hand. If you find that part of the belly hard and resisting, and giving out a dull sound on percussion, you may be sure, in these cases (where there is paralysis of the lower extremities, and the water dribbles away), that the bladder is full, and has lost the power of expelling its contents. Sometimes you may recognize the fluctuation of the urine in the distended bladder, and ascertain the globular shape of that organ. It will rise even beyond the umbilicus. But what I chiefly wished to point out to you is, the circumstance that the bladder becomes diseased, and the urine altered in quality, under this state of palsy. The urine becomes thick, ropy, and alkaline, and exhales a very offensive ammoniacal smell; and the inner surface of the bladder is found, after death, to be thickened, red, and covered with adhesive mucus—in a state of chronic inflammation, in short.

CLINICAL LECTURES,

BY DR. CORRIGAN,

*Delivered at the Hardwicke Fever and Whitworth Hospital, Dublin,
During the Session, 1840-41*.*

LECTURE III.—(FEVER, No. 1.)

Present epidemic a primary or secondary disease? Cases of Geoghegan, Purcell, and of Walsh. Considerations on Pathology in relation to treatment, &c.

It has been observed by Sydenham, and indeed by every practical physician, that the type of fever is frequently changing; and that there is, for the treatment of that disease, no knowledge more desirable than an acquaintance with the epidemic constitution of the time being. Sydenham, one of the most accurate of observers, has further noticed, that when the type changed he was frequently very unsuccessful in his practice,

until observation made him acquainted with the nature and tendency of the new type setting in. We shall devote a sufficient number of our clinical lectures, commencing to-day, to an examination and attentive observation of our present epidemic fever, and endeavour to make our observations as purely practicable as possible, recollecting that the whole and final object of clinical medicine is the treatment of disease. The prefatory observations on the nature of fever I shall make as short as possible. The different opinions as to its nature may be divided into two classes; the first comprising those of, generally speaking, our own physicians, who consider fever as an essential or primary disease; and the second those of many celebrated schools and physicians, among whom is reckoned the celebrated Louis, who considered fever to have no existence as an independent or primary disease; but regard it as the result or consequence of a local disease; and of those holding this opinion, by far the greater number consider typhus as the constitutional disturbance produced by inflammation of the glandulæ aggregatæ of the intestines. Dr. Christison, however, states that Louis has latterly much modified his opinion; and has admitted that typhus may exist without the peculiar affection of the intestinal canal. I think it is hard to contemplate our cases of typhus without coming to the conclusion that our opinion in this country is correct, which views our typhus fever as an essential primary disease, and existing without any local structural lesion.

Let me just recal your attention to the case of Geoghegan, in No. 1. His disease was a well-marked specimen of our maculated typhus fever; we saw him comatose, lying on his back, with muttering delirium; sordes on his tongue and teeth, with a pulse of 132, a skin thickly maculated; with very great prostration of strength, and involuntary stools; with sensibility so much diminished that the eyelids remained fixed, and we were obliged to use the catheter to draw off his urine. A crisis took place; and in less than two days there was nothing to be contended against but debility; pulse became regular, tongue clean, and sensibility natural; sleep returned, and not a trace or symptom of local structural disease of intestinal canal remained. It is not possible to suppose, in such a case as this, that if those symptoms depended on structural disease, or local inflammation, they could so rapidly subside. It is not possible to suppose that local inflammation or ulceration could so rapidly disappear. We do not see, in ordinary cases, local inflammation, even of a slight degree, so rapidly subside; still less of so severe a form or nature as to give rise, according to

* In Dr. Corrigan's last lecture (vol. xxvii. page 907), for "naturalized cells" read "natural-sized cells."

the localizers, to fever, or to symptoms carrying with them such hazard of life.

Contrast, now, Geoghegan's case with Purcell's, in the same ward. In Purcell's there arose, in the course of the fever, an undoubted complication of disease of the mucous tissue of the intestinal canal; but how different has been the progress of the case. His illness has been prolonged, he has lost much flesh, the amendment has been very slow; relapses of diarrhoea and tormina have been frequent, and it is only at the end of some weeks from the termination of the fever that we can now safely pronounce him convalescent. We have, however, still more decisive evidence on this point. Honoria Walsh died on the fourteenth day of fever, with all the ordinary symptoms of severe maculated fever. The immediate cause of her death was sudden effusion on the brain and into the bronchial tubes. She died just at the time when the maculated fever was at its height; and had the fever been dependent on local disease in the follicles of the intestinal canal, we should have found it extensive, or in some degree corresponding either in extent or intensity with the severity of the fever. Instead of this, on a careful examination, we could only find one trifling patch of the glandulæ aggregatæ more slightly developed than natural; but neither redder than natural nor ulcerated. It would be obviously absurd to attribute to a local alteration so trifling as this such tremendous consequences as the production of typhus fever through the whole constitution. It would be out of place here, in a clinical lecture, to go into further proofs of the accuracy of our views of the essential or primary nature of fever, than are furnished by the cases falling, at the present time, under our immediate observation.

Supposing, however, we were even to admit that the local disease could be a cause of those constitutional derangements to which we give the name of typhus fever, let us inquire how far—for this is a very important practical consideration—how far this is to be permitted to influence practice. There is no reflection I know more likely to arise in the mind of the observer than this. Let us learn from pathology the local disease or injury that causes the symptoms or constitutional disturbance. We may then disregard the latter; it is only an effect. All we have to do is to cure the former; when the cause is removed the effect will cease. This sounds very plausible; but the man who would act on it would make a very bad physician. There is no aphorism more true than this: that you may cure a disease and kill a patient. A patient may die cured. Admitting local disease to be either incidentally present in fever, or even going farther, and

granting it, for the sake of reasoning, to be *the disease*, of which the general fever is, but the consequence; still, when you look at a patient, in fever, even if you take this view, you must not forget that there is also the constitutional derangement, and the local alteration, to be taken equally into account, and that even though the constitutional derangement be but an effect, it will often require more of your consideration than the local disease. What would you think of a surgeon who, in a case of calculus in the bladder, or diseased extremity, in which the strength was gone, and constitution shattered, by irritative fever, would proceed at once, utterly regardless of the state of the constitution, or general functions of the system, to operate on this principle, arguing thus: that as the constitutional derangement was only the effect of the local injury, he should therefore disregard altogether the constitutional derangement; that it was only an effect; that he would therefore direct, at once, his whole energy to the removal of the acting primary cause, in the expectation that the removal of the effect would follow. You know what the result would be: his patient would die cured. Now the very same fault would be committed by a physician who, standing at the bed-side of a patient, in typhus fever, would see nearly all the important functions of life deranged, would nevertheless disregard the state of the system generally, and overlooking all this, would fix his attention exclusively on some local alteration, and direct his efforts alone against that. *His patient, too, would die cured.*

Thus, if we even admit the pathology of fever to be, what many of our continental physicians believe, a local disease, we must still be carefully on our guard that this pathology shall not lead us into a dangerous error in treatment. If we admit the existence of local disease in fever even, as an incidental occurrence, or as the primary cause, still let us keep this consideration in our mind:—There is local disease, and there is disturbance of vital functions; from which of these two is the greater danger at the present moment to be dreaded? It may happen that measures against both may be combined; but if not, then it is obvious that if some one or more of the primary functions, on the continuance of the action of which even life depends, be so deranged as to threaten rapid wearing out of life, even though that derangement be but an effect, it claims for the time our first care. It is not from the amount of structural change in the intestines, even admitting this to be the cause of typhus, that a patient dies; it is from the derangement of some one or more of the vital functions. To remove or repair that derangement—to restore or support those

primary functions, then, our efforts in fever must most often be directed, no matter what our views of the pathology of the disease may be. From pathology we cannot deduce our treatment of fever. We have much more than the local pathology (even supposing such to exist) to contend with, and a consideration of the attempts at definition of fever will fix this still more strongly on us. Attempts have been made to define fever. There is great difficulty in the way—a difficulty similar to what exists in the attempt to define inflammation. There can be no definition of inflammation, because what we call by the name is an appearance or phenomenon produced by the lesion of several primary vital functions, of circulation, of secretion, of innervation, &c. These functions are possessed in different proportions by different organs; and hence the phenomenon will present peculiar features, according to the organ inflamed; and not only this, but these different primary functions will even in the same tissue be affected occasionally in different proportions, so that the characters belonging to inflammation will vary even in the same tissue. So it is with fever; several most important vital functions are simultaneously deranged. The cerebral and spinal functions, the respiratory and digestive functions, the functions of circulation and secretion, are affected; but the proportions in which they are deranged will, perhaps, not be the same in any two individuals; and hence the definition, or even the description which applies accurately to one case may not be suited to a second. The fever will derive its most distinguishing character from the function or the functions in which there is the greatest departure from the healthy state. If this cause of difficulty in the way of attempting a definition of fever be admitted, although it will follow that a definition cannot be achieved, still the disease will be easily recognized, and an understanding will be attained of the variations which the disease presents, and which are almost as varied as the individuals attacked. But although the cases may differ from one another in the way described, still they will all agree in this, that all are characterized by disturbance of most of the vital functions without primary local disease. We may have the circulation little disturbed in a case; but, then, we shall have much disturbance in the cerebral and nervous functions. We shall have in another case comparatively little disturbance of the cerebral functions; but there is considerable departure from health in the state of the circulating and secreting functions; and a third case may present its most prominent features in derangement of the digestive functions; but, just as in inflammation, the functions whose sum of derangement constitutes inflammation are so intimately

connected, that, let the first alteration commence in what function it may, all will be soon implicated if the first derangement be continued for any length of time. So it is with fever. The fever may commence, as in common inflammatory fever, with derangement of the function of circulation; but it lasts for a short time only before cerebral and respiratory functions are more seriously engaged; or, as in our present maculated fever: let the disease commence with derangement or depression of cerebral and nervous functions, and, although there is at first little alteration in the circulation, still, if we watch it from day to day, it will become more involved, until at last its disturbance or departure from a healthy state may demand as much attention as the primary derangement of nervous function.

Thus we can, I think, form a correct idea of fever for practical purposes: if, as we stand at the bed-side, we consider it as a disturbance of the whole, or the greater number, of the vital functions:—the vital function, whatever it may be, that is most affected, stamping the peculiar feature on the individual case, and requiring the most attention, always, however, recollecting that from the intimate relation chaining, as it were, those vital functions together, an aberration from health commencing in one will soon run through the whole, and then the fever will present itself in its most terrific form, when cerebral, circulating, respiratory, and digestive functions are all simultaneously and in equal amount deranged. Having now explained the view in which I would wish you to look upon fever, we are, I hope, the better prepared to proceed with our practical considerations.

ON THE COLOURLESS GLOBULES, AND OTHER ELEMENTS OF THE BLOOD.

To the Editor of the Medical Gazette.

SIR,

IF we very narrowly watch the coagulation of a drop of liq. sanguinis, placed between two slips of glass, we first observe the colourless globules swimming in it; and then the formation of slightly opaline streaks and films, which envelop and draw together a great many of the globules: ultimately forming a thin, diaphanous, tough membrane.

If a mass of fibrin, resulting from the coagulation of the liq. sanguinis (Case 9, p. 692, Jan. 1841), be cut into thin slices, and macerated in clean

water for a day or two, it becomes of a pure ivory white; and when examined with the lens, or in the microscope, its texture is seen composed of the minutest granules, intersected by lines, fibres, and filaments, having the toughness, cohesion, and elasticity of organized membrane.

By maceration in caustic potass (liq. potassæ) it becomes in two or three days of a reddish brown colour, and the liquid is tinged of the same colour; it also loses much of its cohesion, and becomes more brittle, breaking short and easily.

If another slice is macerated in strong acetic acid, in a day or two the opaque ivory-white is entirely changed; the fibrin swells a little, and, without losing its figure, becomes quite transparent, forming a clear jelly, which has still more elasticity than the original fibrin, and quite as much cohesion. If a portion of the transparent gelatinous mass resulting from the maceration of fibrin in acetic acid, be examined, it still shews a multitude of fibrous-looking lines and filaments, evincing organized structure; these are mingled with other lines, which result from thicker portions of the mass being pressed together over each other; but the organized fibrous filaments may, by a little practice, be easily distinguished.

When serum is slowly coagulated by heat alone, particularly if about a fourth of its bulk of water be previously added, it forms a soft semi-opaque solid, somewhat resembling soft blanc-mange. If a very minute portion of this coagulated albumen be examined by the lens, pressing the portion quite flat between two pieces of glass, it appears in transparent films or flakes, crossed by little lines, which are caused by the thin films lying over each other. The films are very brittle, having only a slight cohesion or tenacity, and no elasticity, and presenting the same appearance that any other semifluid transparent animal jelly would do. If a drop or two of vinegar be added to the serum before the coagulation; or if the heat be more quickly applied, and no water added, the coagulation is more complete, the mass is more opaque, and is then composed of an innumerable quantity of variously-sized granules and globules, mixed with a few of the transparent flakes; and on pressing

or gently rubbing the two slips of glass together, with a very little of this coagulated albumen between them, these several objects are rendered very distinct by the lens.

On placing a little coagulated albumen in caustic potass, it is entirely dissolved in two or three days, and the fluid is tinged reddish brown. By acetic acid the blanc-mange appearance is altered, and the semi-transparent portions become more opaque.

From the chemical relation and ultimate analysis of fibrin and albumen, they are no doubt modifications of the same animal principle, yet physically, or mechanically and physiologically, they differ most materially.

A minute film of fibrin is not separable into smaller portions, nor is it to be resolved into distinct granules or globules by the firmest pressure, nor by rubbing the slips of glass against each other; repeated washing does not remove any thing from it, nor is it altered by boiling. On the other hand, coagulated albumen is friable, brittle, and has the slightest possible cohesion; the slightest pressure between the slips of glass breaks it down, and resolves it into a multitude of extremely minute detached granules and globules, and flakes, of various forms and sizes.

The blood can hardly be said to be organized, yet, from the physical characters of coagulated fibrin, it is evident that while circulating in the body it holds in solution a peculiarly endowed animal principle (fibrin), requiring only a moment's rest to constitute solid organized (I do not say vascular) tissue. The texture, formation, cohesion, toughness, elasticity, and unalterable condition by boiling, are all proofs of its organized nature; and it at once, without further aid or assistance, assumes all these properties even after its removal from the body in venesection, or after death in its own vessels.

There seems, then, to be but one step between the delicate microscopic capillaries and the fibrin of the blood. The former are minute fibrinous canals, carrying blood; the latter may (not inappropriately) be termed organized tissue in solution, circulating with the blood. Fibrin, then, is the connecting link between the solids and the fluids. As in other departments of

nature we find the most gradual and imperceptible transitions, so it is with the solids and circulating fluids of the living body. The capillary tufts are carried out to such an extent of minuteness and subdivision, that they lose many of the physical characters of a solid; while the blood, circulating with force and rapidity through all these delicate channels, can hardly be preserved from depositing the organized (or organizable) material it so abundantly contains.

Putting out of consideration the minute saline, and other elements of the blood, we may consider this fluid as composed of red globules—a highly organizable and vital form of albumen (called fibrin); and non-vital, or much lower organizable (or organized) albumen. As soon as the blood has escaped from its vessels, or as soon as it ceases to move, the vital albumen becomes solid, by virtue of its vitality assuming an elastic, tough, membranous form; while the non-vital, or less vital albumen, remains in solution with the watery part of the blood, and constitutes the serum. If serum be made to solidify by the application of external agents, such as heat, acid, &c. it forms merely a multitude of irregular incoherent granules.

Fibrin forms the staple material of the elastic tissues of the body—muscular fibre, cellular tissue, and blood-vessels; the interstices and meshes being filled up by the watery portions of the blood, and regular globules of coagulated albumen: for when nature solidifies this material to contribute to build up organized tissue, it is effected by the formation of regular globules, of various sizes.

The agents, therefore, at work in building up the body, and also in the formation of abnormal structure, are the capillaries, the fibrin, and the albumen. The red globules are never found in any normal secretion—except perhaps menstruation—nor are they, in health, in any part out of their proper vessels; their office, therefore, whatever it may be, whether in aiding the endosmosis of the several secretions, or in keeping the fibrin fluid, is confined to the blood; they have nothing to do out of the blood-vessels.

The capillaries constitute the extreme parts, or the limits, of the solid

structures. The albumen is presented to us in solution, in the watery parts of the blood; while the fibrin, which solidifies as soon as it escapes from the channels of the circulation, is peculiarly the connecting link between them. All normal structure is built up by the capillaries, by the fibrin and albumen; and all morbid or adventitious growths and deposits may be classified as more peculiarly belonging to one or other of these important agents. Thus bronchocele, nævus, and scirrhus, arise from too active a state of the capillaries; they branch out, or shoot forth, and organise a mass which is not only not required, but which is prejudicial and destructive of health and life. In inflammatory deposits of lymph, false membrane, and morbid adhesions, we find the fibrin the sole or principal agent; whereas, in tubercle, we recognise the globular, incoherent form of albumen.

In some of these instances the capillaries retain their activity and action for a long period of years, as in bronchocele, and a few other tumors, without any material interference with any important vital function. In other cases, after a pretty active display, for a time they fail in their action, and their abnormal increase is in some places stopped, and they give way, and the skin, or normal structures which they before supported, dies. Hence results the ulceration in cancer, fungous hæmatodes, and other sores. Sometimes in these singular formations there are alternations of their growth, vigour, and decay; or, side by side, the two actions may be going on at the same time: we have then destructive ulceration, as it is called, and fungous growths, alternating with each other; or even in the same sore a fungous capillary tuft may shoot forth in all its activity, forming an irritable red fungus, and yet be surrounded by other decaying tufts forming phagedenic, or cancerous ulceration, where the elements of the blood, in the form of mucus and pus, escapes, or even the blood itself is poured out from the open ends of the decaying capillaries.

WILLIAM ADDISON.

CASES OF
PTOSIS AND ECTROPIUM,

COMMUNICATED BY T. B. CURLING, Esq.

(For the Medical Gazette.)

Double Ptosis and Divergent Strabismus from Palsy of the muscles supplied by the third pair of nerves.—Ptosis on one side cured by operation.

A stout gentleman, æt. sixty-four, a captain in the merchants' service, who had passed forty years of his life at sea, came under my care in January 1841, on account of ptosis of both superior palpebræ. The lids hung loose and motionless over both eyes, and so completely obscured the patient's vision that he was constantly obliged to raise one of them with his fingers in order to relieve himself from blindness. He was also affected with double divergent strabismus, and had lost all power of directing the eyeballs in any other direction, the distortion being fixed and permanent. These symptoms were evidently occasioned by paralysis of the levatores palpebrarum of the inferior oblique, and of the superior, inferior, and internal recti, muscles supplied by the third pair of nerves. The superior oblique, likewise, appears to be paralysed. This affection came on gradually after a fit, and had existed for four years. He had since experienced several slight fits of the same kind; and was subject to occasional twitchings of the muscles of the limbs. Otherwise he enjoyed good health, and had no other symptom of paralysis. He was not subject to pains in the head, and his vision was sufficiently good to enable him to read a moderate sized print. He suffered, however, very great inconvenience from the ptosis, being obliged, whenever he moved about, to keep his hand constantly raised to his head in an awkward and fatiguing position, in order to enable himself to see his way. The paralysis of the affected muscles was so complete, and of so long duration, that I could anticipate no benefit from medical treatment; and consequently none was adopted. I noticed that he constantly made the attempt to raise the lids by putting the occipito-frontalis muscle into strong action, and that, in consequence, the eye-brows had become

much elevated and unusually arched. It occurred to me that if the superior palpebra could be brought under the influence of this muscle the ptosis would be removed, and that he might thereby regain the power of uncovering the eye. The patient being very willing that something should be done for his relief, I performed the following operation. The integuments between the eyebrow and lid, which were very abundant, were raised with the thumb and forefinger of my left hand, and those of an assistant, to such an extent that it was just possible for the patient to close the lids, when, by a single stroke of the scissors, the skin included between our fingers was removed, leaving an elliptical wound which extended from a little below the eye-brow to about one-third of an inch from the margin of the lid and the whole width of the palpebra. Scarcely any bleeding ensued. The edges of the wound were approximated and retained by two sutures, and the part united by the first intention, and perfectly healed in eight days. No ectropium or deformity resulted. The patient afterwards could completely close the lids, and, as was anticipated, could raise the superior one, and uncover the eye, simply by the action of the occipito-frontalis muscle. The vision of the right eye being the most perfect, the operation was performed on that side, and as I found that the sight was confused, and giddiness produced by exposure of both eyes, owing to want of correspondence between the globes, I thought it better not to meddle with the other side. In consequence, also, of the atonic and paralytic state of the other recti muscles, I considered the case unfavourable for the cure of strabismus by division of the rectus externus. The patient, therefore, was obliged, in walking, and at other times, to turn his head a little sideways, an inconvenience to which he soon became reconciled.

A somewhat similar operation has, I believe, been performed by Mr. Hunt, of Manchester, in a case of traumatic ptosis of one lid, consequent upon a division or laceration of the levator palpebræ muscle; but I am not aware of its having been practised in any case of paralytic ptosis. The above case shews, however, that the operation is equally applicable to the latter form of

the affection, and that it may be undertaken with a confident reliance on the occipito-frontalis muscle being afterwards adequate to elevate the drooping lid.

Case of Ectropium consequent on the contraction of the cicatrix after a burn, cured by operation.

A servant girl, aged sixteen, applied to me for removal of the deformity produced by eversion of the upper lid of the right eye. She stated that six years ago she had met with an accident by which she received a severe burn on the face and scalp, and afterwards, as the sore healed, the lid gradually turned out. There was considerable eversion of the lid, chiefly towards the outer angle, and the mucous surface presented a prominent granular appearance of a deep red colour, which was very disfiguring to the countenance. The skin above was very tense, the eyebrow was completely destroyed, and there was an extensive cicatrix on the forehead, right temple, and side of the face. The integuments, however, were not adherent to the frontal bone. She was unable to close the lids completely, so that she was constantly subject to attacks of conjunctival inflammation from the effects of wind and dust. On this account, and as the unpleasant deformity rendered her such an object of aversion to her fellow servants, that she found great difficulty in getting into service, she was very anxious to undergo an operation for relief. I made a semilunar incision through the integuments along the upper and outer edge of the orbit, so as completely to set free the palpebra. The upper lid could not, however, be restored to its natural position, or brought into contact with the lower, owing to the protrusion of the granular and thickened conjunctiva. This membrane was freely excised with a pair of curved scissors, in the performance of which a small portion of the tarsal cartilage was cut away. The lid then covered the eye in a natural manner. After the bleeding had ceased the external wound was dressed with dry lint. At the end of a week both wounds had assumed a healthy granulating appearance. The healing of the external one was checked by the application of a plaster made of cantha-

rides. Notwithstanding this, both wounds completely healed in sixteen days after the operation. The cicatrix in the conjunctiva fully succeeded in counteracting the contraction externally, and in preventing the return of the eversion. The girl was consequently greatly improved in appearance. The lids could be brought much closer together, sufficiently so as to prevent annoyance from foreign substances coming in contact with the eye, but could not be perfectly closed; the margin of the upper lid having assumed somewhat of an arched form, owing to previous elongation. This, however, was diminishing when the patient returned to service.

The particulars of this case may prove interesting, as that form of ectropium occurring after burns is one of the most difficult to cure, and as the operation which succeeded was a very simple one. I at first contemplated removing a wedge-shaped portion of the eyelid, in order to counteract the morbid elongation, but afterwards abandoned it; and I am inclined to think that this proceeding may often be spared; and that in many cases, as in the above, after the removal of the eversion, and obviating the causes tending to produce this deformity, the lid will gradually resume its natural form.

In connection with the subject of ectropium I may detail the following case:—

Frightful deformity and destruction of both eyes from double ectropium, consequent upon cicatrization of an extensive burn.

A poor Irish woman has long been in the habit of visiting the London Hospital under the following painful circumstances:—She has been subject to fits since her infancy, and some years ago during an attack she fell into the fire, and her cap and clothes catching fire, she sustained a severe burn on the head and face. The greater part of the scalp, including both eyebrows, was completely destroyed. After the separation of the sloughs, as the wounds began to heal, the eyelids on both sides became gradually everted. This was particularly the case with the upper lids, which were remarkably stretched and drawn upwards, to compensate for the extensive loss of the cutaneous

tissue on the head. Inflammation of the conjunctiva was necessarily the result. In the right eye, the inflammation extended to the interior of the globe, caused suppuration, and the destruction of the organ: the collapsed tunics of which still remain at the bottom of the exposed orbit. In the left eye, conjunctival inflammation has produced prominent staphyloma of the whole cornea, and entire loss of vision. The destruction of the scalp was so extensive, that the parts remained unhealed for several years, presenting a suppurating sore, which assumed sometimes a healthy character, and at other times an unhealthy and ulcerative surface, according to the varying states of the patient's health. The cicatrix on the head presents a pale, smooth, glistening appearance, and is extremely tense. The exposed conjunctiva of the lids of both eyes has a red granular aspect, and is constantly discharging. The everted upper lid forms a red conical patch above the orbit on each side of the forehead. It may easily be conceived that the deformity consequent on the state of parts just described is of the most hideous and painful character. In addition to loss of vision, the poor woman is a severe sufferer in other respects. She continually experiences a distressing sense of constriction in the cicatrix, which sensation is increased whilst the part remains healed. So forcible, is the contraction that the surface of the skull beneath presents a number of irregular projections, owing to partial atrophy of the bone from pressure. The sore on the head occasionally ulcerates, and is rendered painful, and the unprotected conjunctiva is constantly subject to become irritated and inflamed from the contact of foreign bodies, notwithstanding the means taken to obviate these annoyances. Her general health is a good deal impaired. Such has been her state, with little variation, for seven years, during which she has been under my observation; and it has rarely been my lot to witness a more truly distressing case, in which so little could be done in the way of relief.

1, Mount Place, London Hospital,
March 6, 1841.

ON SUBCUTANEOUS OPERATIONS IN SURGERY.

By ROBERT HUNTER, M.D.

Professor of Anatomy, Andersonian University,
Glasgow.

[For the Medical Gazette.]

THE range of subcutaneous operations has, till lately, been much circumscribed, extending chiefly to the section of a few of the muscles of the body, and to the evacuation of certain abscesses and cysts; but such operations appear to me of immense value in surgery, and worthy of a more extended and diversified application. The advantages of the subcutaneous plan of operating, over the common method, may be comprised in the following particulars: 1st, less infliction of pain; 2d, less subsequent inflammation; 3d, no suppuration; 4th, little or no constitutional disturbance; and, 5th, a rapid return of the parts operated upon to their normal condition.

We all know the dangers attending the incautious opening of a psoas abscess, and the advantage to be derived from the partial application of the subcutaneous plan, as recommended by Mr. Abernethy; and those who have seen the subcutaneous section of the dorsal muscles, as performed for lateral curvature of the spine, and watched the progress of such cases, can speak of its paramount superiority. I have now performed the last mentioned operation twenty-five times, and watched carefully the results, and although, in five of the cases, the latissimus dorsi, the serratus posticus inferior, the longissimus dorsi, and sacro-lumbalis, were divided, and the subcutaneous incision extended from the spinous process of one of the lumbar vertebrae across to the outer margin of the sacro-lumbalis, dividing the above-mentioned muscles, yet the pain was so trifling that the majority of patients hardly murmured. The flow of blood never exceeded a few drops. The skin over the track of this long and deep incision never changed its natural temperature or colour; in no case did suppuration follow; constitutional disturbance of any kind never once supervened, and in three or four days after the incision the puncture had cicatrized, the swelling from the effused blood had generally disap-

peared, and frequently by that time not a vestige of the operation could be discovered. During the time I sojourned in Paris last summer, M. Jules Guérin operated upon a patient affected with ankylosis of nearly all the body, arising from contraction of the muscles. He cut across forty-four muscles, and spread out the limbs, and although the successive incisions occupied more than sixty minutes, yet the system of the patient received so small a shock, that the pulse was not sensibly affected, and the patient slept soon after the operation, and neither irritability nor febrile excitement followed.

I attribute the mildness of the effects of subcutaneous operations to two causes: 1st, to the exclusion of the atmospheric air, and, 2d, the small injury inflicted upon the highly organized and sensitive structure of the skin.

That the atmospheric air will excite irritation and suppuration on the surface of a wound is a matter of daily observation. When the cuticle only is removed from a blistered surface, an immediate accession of pain is the consequence, and the serous effusion is also speedily changed into the purulent. If the atmospheric air, then, is capable of acting as a source of irritation, and if a wound of the skin is the more painful and the more dangerous as it is the larger (and of this last there can be no doubt), it follows that, in the performance of subcutaneous operations, regard should be had to two circumstances—1st, the puncture through which the instrument is carried under the skin should be as small as is compatible with the due performance of the other steps of the operation; and, 2d, means should be used for preventing the accession of atmospheric air both during and after such operations.

In the further prosecution of this subject, I shall shortly advert, 1st, to the cases in which subcutaneous operations have already been advantageously applied; and, 2d, to those affections to which, I think, they may with propriety be extended. The first division may be said generally to include two classes of morbid affections: those on which the muscles or their appendages are chiefly concerned or implicated, and those in which fluids require to be evacuated; and the second division will probably, at no distant

period, be found to include a long, but at present indeterminate, list of diseases.

1st. *Diseases which have been treated by the subcutaneous operations, and for which this plan of treatment has been eminently successful.*—At the very top of this class I would place such affections as require for their treatment the section of muscles or their tendons. The muscles are peculiarly adapted for the subcutaneous operations, their situations, forms, and relationships, are so easy determined; and when their section is required, the resisting nature of the texture to be divided, render all such operations, even though under the skin, at once safe and simple. Such sections are now in daily use in wry-neck, certain curvatures of the spine, muscular stiff joint, club-foot of every kind, and I must also add strabismus; for although the operation for that affection is at present performed without regard to the subcutaneous principle, still it cannot be viewed as a perfect operation till that principle is adopted, which, I think, it is likely to at no distant period.

I believe I was the first in this country to perform the subcutaneous section of the dorsal muscles for the cure of lateral curvature of the spine, and as I have now had some experience upon this subject I shall lay the result of my observations briefly before your readers. In no instance has the operation of *itself* produced a cure; but in all the cases on which I have operated, with one exception, it manifestly placed the patient in a more favourable state for the performance of a cure. The operation itself appears to me to effect no more than to take off, either in part or whole, the power of muscles that are interested in maintaining the curvature, and thus placing the spine in a condition to be more easily influenced by mechanical and physiological causes.

The cases which have been treated by me have all been of long standing, none less than seven years, and some ten, sixteen, and twenty years, and all with considerable torsion and gibbosity, as well as lateral curvature. In fact, they were cases which were either considered absolutely hopeless, or on which medical skill had been exerted for years without the slightest benefit. In some instances the section of the muscles was instantaneously followed by

an obvious improvement in the state and appearance of the back; in other instances I could discover no change whatever.

I perform the subcutaneous section of the dorsal muscles at four different places of the back. 1st, I weaken the tension of the deepest seated layer of muscles—that formed by the multifidus spinæ—by dividing the thickest part of that muscle, as it lies comparatively superficially upon the dorsum of the sacrum, opposite the posterior superior spinous process of the ilium. 2dly and 3dly, I remove the tension of the middle layer of spinal muscles, that formed by the longissimus dorsi and sacrolumbalis, by cutting these muscles across, sometimes in the lumbar region and sometimes in the costal region, according to the circumstances of the case; but more frequently in the lumbar region, near the origin of these muscles. 4thly, to destroy the tension of the flat and more superficial muscles, I divide these muscles by a longitudinal incision, close to the spinous processes of the vertebrae, at the place where the tension of these muscles appears to be the greatest. In one instance I cut through, with considerable effect, the *latissimus dorsi*, at the side of the chest, and consequently at some distance from the spine. The muscle crossed the contracted and concave side of the trunk, and appeared to be accessory in huddling in the ribs of that side. When the patient attempted to elongate that side, a cord, as thick as the little finger, was seen stretching from the crest of the ilium to the scapula: as soon as this rigid cord of muscle was cut through, the ribs became less huddled together, and the side could be elongated to a much greater degree, and the spine materially affected.

In cutting the dorsal muscles I have chiefly, though not exclusively, followed the method of Guérin. Guérin employs always two instruments; I have frequently employed only one: Guérin uniformly cuts the muscles by commencing at the cutaneous surface of the muscle, and proceeding deep-seatedly; I have repeatedly and with greater safety cut in the opposite direction, that is, by carrying the instrument more deep-seatedly than the muscle, and cutting towards the skin. As Guérin, however, is a great authority

upon this subject, his mode of operating is worthy of being mentioned. He makes the subcutaneous incision with a narrow sharp-pointed bistoury, about two inches and a half in length. He then withdraws that instrument, and introduces into the track thus made a sickle-shaped instrument of the same length and breadth as the former, the cutting edge of which is on the convex margin. Having carried this instrument across the muscles to be cut, he turns the convex cutting edge to the muscles, and their division is effected not by one cut but by a number of successive touches, the patient at the same time calling his dorsal muscles into action by throwing his head forcibly backwards to impart a greater degree of resistance to the muscles, and to enable the incision to be effected partly by the pressure of the contracting muscles upon the edge of the knife.

The cutting of the dorsal muscles is only the first, though an important step in the treatment of spinal deformities. The means that are afterwards employed in conducting such cases to a successful issue are both mechanical and physiological. The first consists in the application of pressure, made in various ways and by various means to assist in the gradual return of the parts to their natural places, and the second, without which the first would be useless and unavailing, consists in infusing power into the muscles which have become weak or dormant from disease, by simply calling these muscles frequently and in various combinations into action.

If I mistake not, I was the first likewise in this city who performed the subcutaneous section of the muscles for the cure of club-foot. I have seen the operation performed by M. Guérin for valgus varus and equinus, and with astonishing success. I have performed the operation on three patients, all of whom were affected with varus. Two of these patients were infants, and the third a female about thirty years of age, who had been deformed from birth. The sections of the tendones-achilles in the infants enabled me at once to bring down the heels, and to place and maintain the feet in their natural position by an appropriate apparatus. In the adult the deformity was very great—a varus,

as Guérin would express it, in the third degree; that is, the heel was raised, the foot thrown transversely inward or to the opposite foot and laid upon its fibular margin, and lastly the toes turned into the sole of the foot, and the foot itself curved from the great toe towards the heel.

In this case I first cut through the tendo-achillis, which permitted the heel at once to descend; I then divided the tibialis anticus muscle, which was extremely rigid and short, the section of which was attended with a very loud crack. The division of this tendon did not, however, effect so much benefit as I was led *à priori* to expect. The foot still continued turned much inwards, and the gathered-up state of the foot itself not at all improved. To overcome the still remaining obstacles I cut through, by one subcutaneous incision in the plantar aponeurosis, the abductor pollicis, the flexor brevis pollicis, and the long flexor of the great toe, and the effect was immediate and remarkable. The foot, which before had as much the appearance of a closed fist as of a foot, at once assumed its natural character. The toes were turned forwards, and more spread out; the heel down, and the sole of the foot flat, and turned to the ground. The patient, delighted with the effect of this last incision, exclaimed, "Doctor, this is the best cut of all!" After the operation, Mr. Campbell, surgeon, in Calton, to whom the case belonged, and who assisted me in the operation, placed the foot in a very simple apparatus which he had previously prepared, but which fulfilled all the indications required in the treatment of such cases, viz. to maintain the foot fairly upon its sole, with the heel down, the toes turned forwards and a little outwards, with the free play of the ankle-joint. It is now seven weeks since the operation was performed, and the case I am enabled to state is progressing most satisfactorily.

The evacuation of fluids enclosed in cysts has also for some time been effected upon the subcutaneous principle, and probably the practice is applicable, in a greater or less degree, to encysted tumors of every kind; psoas abscess should invariably be evacuated in this way, and circumscribed abscess of a specific or unhealthy nature might be treated in a similar manner. My

friend and colleague, Mr. Watt, has for some years been in the practice of evacuating the matter of bubo on this principle. He introduces a narrow lancet through the sound skin at a little distance from the bubo, and carries the instrument under the skin till it nearly touches the abscess. He then withdraws the lancet, and carries into the track thus made a grooved needle, with which he penetrates the sac. The matter then flows along the groove of the needle till the abscess is sufficiently emptied. The needle is now withdrawn, and a small bit of gold-beater's leaf accurately and elegantly closes the external aperture. In this way the matter may be removed as often as required, followed by no ulceration of the integument, no open and intractable sore, and no subsequent unseemly cicatrix.

Ganglia and melicerous tumors have also for some time been treated by the subcutaneous operation, both with safety and great effect. Dr. Cummin, formerly of Glasgow, was among the first to recommend the adoption of this practice. His plan consisted in introducing a cataract-needle under the skin for some way, then transfixing such tumors, and pressing the fluid into the surrounding cellular tissue. The cyst may thus not only be transfixed in different directions from one puncture of the skin, but its inner surface freely scarified, or deeper incisions made, so as to destroy the integrity of the secreting membrane, and give to the fluid an easy exit into the surrounding cellular texture.

By an easy gradation a similar practice may be extended to tumors of various kinds, particularly those of a simple and non-malignant nature, dependent for their vitality and growth on the surrounding cysts. Thus in an adipose, atheromatous, or steatomatous tumor, the introduction of a cataract-needle, so as to destroy the natural cohesion of its parts, or, as some would express it, its organization, and break up at the same time its cyst, might be the means of procuring the death and ultimate absorption of such a tumor, and thus save the pain and disfigurement of extirpation. Some years ago, the late Mr. George Macleod, of this city, stated, that he had been successful in dissipating tumors of the eyelids in this manner, and if I mistake

not, he proposed to apply the practice to tumors of every kind. I do not think this practice should be resorted to in carcinomatous or malignant tumors of any kind; total extirpation of the diseased mass is then indispensable, though unfortunately not always a permanently successful mode of cure.

2d. *Diseases to which the subcutaneous mode of operating may be extended.*—I am strongly impressed with the idea that, as surgical science advances, the principle upon which subcutaneous operations are performed will be more favourably regarded, and the operations themselves, under various forms and modifications, successfully applied to the treatment of numerous and diversified surgical affections. At present I can venture only to refer to a few morbid conditions which, from analogy, or the nature and structure of the parts proposed to be operated upon, appear to me adapted for such an operation.

1st. Subcutaneous incisions might be used in the treatment of inflammation of the fibrous membranes of the body at any place where these membranes are situated, from the inner surface of the skin to the exterior surface of the bones. In inflammation of these membranes, or in the parts immediately under them, the pain and intensity of the inflammation are subdued by incisions through these membranes. This is well known, and has been long acted upon. But the practice of the present day is to involve also the skin in the operation. In fascial, and subfascial inflammation, as well as in peritonitis, and all diseases of this kind, we make a free incision through the skin; not that the skin is the seat of the disease, or even materially affected, but apparently for the purpose of reaching the seat of the disease; as if the necessary incision through the deep-seated textures could not be effected without first seriously injuring the cutaneous investment. The object of these incisions is twofold; to unbridle or remove tension from certain parts, and to unload the vessels of the textures affected. Both of these objects could obviously be gained by the subcutaneous operations. In fascial and subfascial inflammations, in peritonitis, paronychia, and other diseases implicating directly or indirectly the white fibrous membranes of the body, I would propose, then, to incise these membranes by introducing a narrow

sharp-pointed bistoury, or other instrument adapted for the purpose, under the skin—an operation which can in all cases be easily performed, which would occasion little pain, which would fulfil the indications required, and produce no external disfigurement. 2d. In inflammation of the skin itself these operations might be useful. In phlegmonous and circumscribed erysipelatous inflammations, in particular, this treatment might be adopted. Instead of the application of leeches to the skin—instead of numerous punctures with the lancet, or long incisions through the skin, as recommended by Mr. Hutchison, and daily used in the treatment of erysipelas, I would propose to scarify the inner surface of the skin—an operation which would be attended with less pain than the incisions at present in use—which would affect vessels the opening of which would have a much more controlling influence over the inflammatory action than the ordinary applications to the free surface of the integuments. In the early stages of phlegmonous and erysipelatous inflammations, and in various kinds of cutaneous eruptions, I would introduce a small lancet or cataract needle through the skin, near the point where the inflammation first appeared, and scarify freely the inner surface of the chorion. This would unload the vessels into the subcutaneous cellular texture. The effused blood thus produced would moderate, I presume, in various ways, the cutaneous inflammation: by the quantity of fluid effused; by the mechanical compression which the effused fluid would have on the vessels entering the inner surface of the skin, and probably also by the stimulus to the process of absorption which the effused fluid might superinduce. 3d. Hydrops articuli, and purulent effusions into the joints, might be relieved or cured by the subcutaneous operations. When the dropsy of a joint is not speedily relieved by general or such local treatment as blisters, compression, or friction, I would recommend the employment of the subcutaneous puncture, and allow the fluid to drain into the subcutaneous cellular membrane, as in the plan now so successfully followed in the treatment of hydrocele.

There is an inherent dread in the profession of exposing the cavity of any large articulation; and this appre-

hension of danger has, I have no doubt, frequently prevented the necessary evacuation of fluids that were straining the textures, and otherwise producing, mechanically, local and constitutional disturbance. But the danger arising from the penetration of a joint is always in the ratio of the degree of communication of the atmospheric air with the cavity of the joint. If the joints are opened with a due regard to the exclusion of the atmospheric air, the risk of danger is not great; probably not greater than that attending the subcutaneous incisions of muscles. I draw this conclusion from actual observation. I have seen M. Jules Guérin frequently cut across the lateral ligaments of the ankle and knee, and penetrate these articulations, in his subcutaneous treatment of deformities of these joints, and in no instance did the slightest bad consequence follow. Guérin, in his lectures, states that he is in the daily practice of performing such operations, and that his practice is not only free from danger, but eminently successful. In penetrating the cavity of a joint for any necessary purpose, the openings through the skin and capsule should be small, and never directly opposite each other. In opening the knee-joint, for example, for the purpose we will suppose of removing a dropsical effusion, I would introduce a slender sharp-pointed bistoury or cataract needle through the skin at the lateral and lower part of the ligament of the patella; I would then carry the instrument directly upwards under the skin, for an inch, or an inch and a half, penetrate the capsule, and with greater or less freedom, according to the degree of viscosity of the contained fluid: I would then withdraw the instrument, close up carefully the puncture in the skin, and by pressure assist in forcing the fluid through the opening thus made in the capsule into the subcutaneous and neighbouring cellular texture.

In tapping for dropsy of every kind regard might be paid with advantage to the subcutaneous mode of operating, even where the fluid, from its situation, quantity, or the nature of the cause producing it, requires to be drawn off entirely and directly from the system. The ordinary or direct mode of tapping for ascites is sometimes followed with inflammation of the peritoneum; but if

a small trocar and canula were used, and the instrument carried for some distance under the skin before the abdominal cavity was penetrated, such an accident could hardly occur.

4thly, The treatment of varicose veins by the subcutaneous incision would, I think, be an improvement in surgery. The ligature on such veins is apt to excite phlebitis, with its train of dangerous and often fatal symptoms; and although the cutting across of these veins, as performed in the usual mode of operating, is a practice not free from danger, yet I conceive the danger would be much lessened, if not entirely removed, by introducing a slender instrument, such as a cataract needle, an inch at least from the vein to be cut, and dividing the vein with the least disturbance possible to the adjacent parts. This view is strongly corroborated by the fact that the application of the ligature, even upon the subcutaneous principle, to certain varicose veins, is attended with little or no danger. I have seen Ricord, of Paris, apply the ligature to the spermatic veins for varicocele; and in September last he had performed the operation twelve times without one unsuccessful result.

5thly, Neuralgia may also be treated with effect upon the subcutaneous principle. In the surgical treatment of this disease the object is to divide the affected nerve with as little external disfigurement as possible. This remark is particularly applicable to neuralgia of the fifth pair. Some years ago I was called to a case of *tic-douloureux* of the infra-orbital nerve. An attempt, I learned, had previously been made to divide the nerve, and the cicatrix which presented itself resembled more the mark of a sabre-wound across the face than the effect of a delicate surgical operation. Since the occurrence of that case I have inculcated the propriety of dividing the branches of that nerve without disfiguring the countenance, and have shewn how this could be accomplished by introducing small instruments of a particular form, either through the skin, or, so far as the infra-orbital and mental branches are concerned, through the mucous membrane of the mouth. This last mode I consider in some respects superior to the other, as the skin of the face is left entirely untouched, the atmospheric air

more effectually excluded, and the nerves divided probably with less pain, at all events with more facility and certainty.

Such is a short list of cases to which the subcutaneous operations have been, or I presume may be, extended. In the greater number of these cases I have either performed the operation myself or seen them performed by others. Or, where the suggestion is entirely novel, or the practice not yet introduced, I have either proved its practicability on the dead subject, or satisfied myself of its applicability to the cases in question, from reasoning, and the light of analogy.

33, North Hanover Street, Glasgow,
6th March, 1841.

ON HIP DISEASE AND LUMBAR ABSCESS.

By WM. OLIVER CHALK, ESQ.

Resident Surgeon to the Royal Sea-Bathing
Infirmary, Margate.

[Continued from Vol. XXVII. p. 949.]

As real shortening of the limb is uncommon without dislocation of the femur, I shall take this opportunity of relating another instance; the only one, with the exception of those already mentioned, that has come under my observation. The case is highly interesting, from my having been enabled to watch its progress during a period of five years, and from the complications that have arisen during that time. T. E. King, *æt.* 5, admitted June 20th, 1836, suffering under disease of the right hip. The local symptoms were as follows: fulness of the nates, with perceptible fluctuation behind the great trochanter; the limb was drawn up and shortened to about an inch and a half; the toe was everted; pain in the groin sometimes acute, particularly when recumbent. Percussion over the trochanter caused great suffering; any attempt at walking produced much inconvenience. His general health was greatly impaired; he was labouring under febrile symptoms. The pulse was quick; skin hot and dry; the tongue covered with a thick white fur; great irregularity of the alvine secretions; severe pain on pressure in epi-

gastrio: there was a remarkable malformation of the chest, the xyphoid cartilage being, as it were, pressed inwards, forming a deep hollow. His mother stated that about Christmas, 1835, he began to complain of fatigue after walking, and that whenever she moved him he cried from pain: he walked with the toe everted, and dragged the limb after him. It was in the month of February that she first observed the swelling of the nates. About five months previous to the appearance of the local disorder he had an attack of scarlatina, which was short in its duration; but it had scarcely subsided when whooping-cough appeared, and lasted for twelve weeks. About this time he suffered repeated attacks of thoracic inflammation, which left him in a very debilitated state. In the May following he was attacked with measles, from which he recovered shortly. He came to Margate in that month, and in June, as already stated, became an out-door patient. His mother attributes the local disease to an accident which happened whilst lifting him out of a warm bath, in doing which the limb was suddenly twisted; he suffered great pain at the time, but it soon passed off; shortly afterwards, however, the symptoms just now described ensued. My attention was first directed to the state of his general health.

Leeches were applied to the epigastrium, followed by a blister; aperients of calomel and jalap were ordered twice a week, and the bowels were frequently evacuated with enemata of warm water. He took a mixture of Liq. Ammon. Acet. and Tartarized Antimony; these, together with a strict antiphlogistic regimen, were persevered in until the febrile symptoms were subdued. The warm salt-water bath was used at intervals, as the circumstances of the case would admit, and formed the only local treatment at this time. His general health, together with the local symptoms, soon improved. The treatment was persevered in, with occasional intermissions, up to August 20th. He now took a mixture of Iodide of Potass and Cinnamon-water (2 grs. to the \mathfrak{ss} .) three times a day, which he continued up to September 13, when the Decoct. Cinchonæ was substituted for Aq. Cinnam. The bowels were at this time inactive, and the excretions still un-

healthy, to obviate which he was ordered occasional doses of Pulv. Scammon. Co. and Pulv. Jalapæ Co., and to persist in the use of enemata. On the 22nd of October he began to complain of pain in the left knee, which soon became somewhat swollen, accompanied by slight heat. Flexion and extension produced inconvenience, and he generally kept the knee extended. He was discharged at the closing of the House, October 28th, having on the whole derived great benefit.

As I was interested in the case I continued my attendance. In the course of two or three weeks the affection of the knee-joint increased rapidly, and soon presented all the symptoms of acute synovitis. The pain became so great that he could not bear the slightest movement, or even the pressure of the bed-clothes: the heat and swelling increased; the limb was now rigidly extended; his nights were sleepless. These symptoms were accompanied by intense febrile accessions. Leeches were again applied to the epigastrium, and a strict antiphlogistic treatment once more adopted. Cold lotions were applied to the knee, and every means used to maintain the limb in a state of perfect quietude. It was some weeks before the synovitis yielded to this treatment, and when it did he began to complain of pain about the hip on the same side: a few leeches were applied in the vicinity of the joint, followed by the application of ioduretted lotions. It is unnecessary to follow out the treatment any further at this period; and it need only be said that by constant and unremitting attention, and by the aid of tonics of Bark, Inf. Gent. Co. &c., together with a generous diet of meat, wine, porter, &c., he recovered slowly from these symptoms, and was readmitted as an outdoor patient, May 19, 1837, greatly improved in every respect, and was discharged the 18th of October following. His health was excellent at this time; he did not suffer any pain in either hip or knee-joints, and could walk tolerably well on crutches. The right limb was everted and shortened to about an inch and a half; the left limb was still extended: the thigh could be bent on the pelvis, and extension made without causing any pain. Soon after his return home I observed

that the nates on both sides were becoming fuller; fluctuation was more apparent on the right side (the first affected), whilst it was sufficiently perceptible on the left. He was still allowed to move about on his crutches, as he suffered no pain. As the suppurative process proceeded I applied an ointment of the iodide of mercury (5 grs. to the oz. of lard) spread on lint, over each swelling, every night at bed-time, in order to decrease the size of the abscess by means of partial absorption: this was effected to a certain extent. When the ointment caused too much irritation on the skin, or any tendency to iodism was evinced, it was omitted for a time. Within about a month from the period of the opening of the abscesses, which occurred in the first week of the April following, 1838, the only local application used was a rag moistened with water, and covered in with oiled silk: the matter on the left side was first discharged from a small orifice, which formed of itself on the upper and outer side of the thigh, and about half a pint of serous fluid, with a slight admixture of tuberculous matter, escaped: about three days afterwards the abscess opened on the right side; the discharge being precisely similar to the other, but less in quantity. He was again received at the Infirmary, July the 25th. The wounds were still open: by the end of June following, that on the right side had healed, but the left orifice was discharging rather profusely at the time of his return home Oct. the 17th. It closed shortly afterwards. On the ensuing 5th of Nov. I was suddenly called to see him: his mother had taken him a day or two before to Hackney in a cab: he complained of considerable pain from the jolting of the vehicle, at the upper and inner part of the thigh, which continued to increase up to the time of my visit. On examination I found a tumor about the size of a large orange, with great heat and redness, and a sensation of acute throbbing: it was evident that suppuration was taking place with great rapidity. These symptoms were accompanied by irritative fever, great thirst, and heat of skin: pulse above a hundred beats in a minute: the suppurative process was soon completed, and about four ounces of healthy pus discharged: the abscess healed in about a fortnight, and un-

der suitable treatment he soon recovered his health and strength. He was again admitted, as an out-patient, June 20, 1839. He could now walk with a stick, but in a very awkward manner,—both limbs being everted. He underwent a course of bathing, chiefly the douche, warm and cold, applied over the hip-joints. He took Decoct. Cinchonæ at times, and was still allowed a generous diet: the bowels were carefully regulated as before. He left the infirmary October 21st, greatly improved in every respect. From this time I saw little of him until Nov. of the year 1840, when I was requested by his parents to examine him. I now found a fluctuating swelling immediately behind the great trochanter, and it was evident that suppuration was going on. Upon making inquiries into the cause of this, I learnt that he had received a blow from one of his school-fellows just above the popliteal space, which he said caused some slight pain about the hip at the time: this happened about five or six weeks previous to his leaving Margate in Sept. last. He suffered scarcely any pain or inconvenience during the formation of the abscess. A small quantity of whey-like fluid was discharged recently from an opening in the situation of the former cicatrix, which has since ulcerated to about the size of a shilling, and at the time of writing this is nearly healed. He now walks on crutches without any inconvenience; they are used for the sake of guarding against accident, rather than from any inability to do without them. I have recently examined both articulations; he has recovered the use of them. The trochanter of the right side is considerably higher than natural, being scarcely more than an inch from the crista ili, yet the shortening of the limb is now scarcely perceptible: there is no eversion of either foot. He suffers no inconvenience about the left knee, and the action of the joint is perfect. It cannot, I think, be doubted that the neck of the femur is altered in its position, as in the case of H. Eagle; the form of the nates and the situation of the trochanter being precisely similar. Suppuration cannot have taken place within the capsule of either joint, otherwise their action could not have been restored. It will be remembered that the abscess formed

on the left side soon after the synovitis of the knee: in all probability the suppuration was sympathetic: it was also more superficial; and although it formed full six months subsequent to that on the right side, was the first to break. The constant tendency to the formation of matter on the occurrence of the slightest injury in this case is remarkable; in proportion, however, as his general health improved, each recurrence of the local disease was less severe. The constitutional symptoms having now subsided, there seems to be little doubt of his ultimate recovery.

It would appear from the two following cases that dislocation of the head of the femur from the cotyloid cavity may take place independent of any disease of the articulation itself, from position adopted by the patient for the relief of other parts:—

John G. Butter, æt. 13, admitted May 9, 1837, suffering from necrosis of the left tibia, osteitis of the left sterno-clavicular portion of the left clavicle, and from a small strumous ulcer on the chest: previous to his arrival he had experienced an attack of rheumatic fever, and the leg had been severely affected. There was partial dislocation of the head of the femur, which could be distinctly felt resting on the rim of the acetabulum: the limb was lengthened to about an inch and a half. He had never suffered the least pain in the articulation. During his illness he had been in the habit of crossing the leg affected as far over to the sound side as possible. He left the infirmary Oct. 21st, quite well, the head of the femur having regained its position, slight weakness of the extremity alone remaining.

Wm. H. Elsworthy, æt. 14, admitted Sept. 8, 1837, suffering under necrosis of the left tibia, consequent on rheumatism, with dislocation on the dorsum ili; the limb was turned inwards, and was considerably shortened: the head of the thigh-bone could be distinctly felt, and it was exceedingly moveable. He had never suffered any pain in the articulation, nor could he or his friends say how or when the dislocation took place. He left the infirmary October the 27th, the local disease being somewhat ameliorated, and his general health improved. It is curious that in both cases the dislocation should take

place as a consequence of necrosis of the tibia. There cannot, I think, be a doubt that the capsular ligament must have undergone elongation, (particularly in the latter case), as mentioned by Mr. Stanley, in a paper already alluded to; and this circumstance, together with the position and atrophous state of the muscles consequent on emaciation and inactivity, must have combined to produce luxation.

The diseases with which morbus coxae may be confounded, such as hamorrhoids, sciatica, &c. &c. have been ably described by Sir Charles Bell, but by far the most serious and most important to distinguish is psoas abscess. I will, however, take this opportunity of relating a case of simulated coxalgia from the presence of a foreign body, as it is the only one I have ever met with, and may serve to place us on our guard when examining these cases. Ann Harrison, æt. 22, admitted July 23d, 1839. The patient stated that she had been suffering under disease of the right hip-joint for five months past, which originated in a fall from her chair on the 11th of March last. The limb appeared shortened: when she stood on her crutches the toe scarcely touched the ground. The shortening arose from contraction of the knee-joint: flexion, extension, rotation, &c. gave no pain, nor was there any on percussion over the articulation. Whilst under examination she called my attention to a particular spot behind and rather below the great trochanter, which she said was always excessively painful when touched. At this point I found a small rounded body about the size of a pea, which seemed immediately beneath the integuments. Her general health was much deranged; pulse quick and feeble; tongue furred; bowels costive; great tenderness in epigastrio, as well as in the flexures of the colon. She had lately suffered from hectic fever. The catamenia had been suppressed for several months. Her health had been delicate prior to the accident. My attention was first turned to the relief of the general symptoms. The hepatic treatment was adopted, and her health soon underwent an obvious improvement.

I could not satisfy myself as to the precise nature of the local symptoms, and I therefore determined on a closer

investigation of them*. By careful questioning, I found that she was doing some needlework at the time she overbalanced herself. In falling she remembered to have felt a snapping sensation in the hip, followed by acute pain, which she always referred to the spot already mentioned. She did not apply for advice until the end of the week following the accident, when a medical gentleman was called in. Leeches were applied to the hip, followed by a blister, and these means were persevered in, at intervals, up to April 16th, when, having derived no relief, she entered a hospital. A large blister was now placed over the articulation, and kept open. Leeches, to the number of seventy, were applied at different times; she was strictly confined to the recumbent position, and a suitable medical treatment adopted. At the end of eight weeks, the symptoms being somewhat abated, she was allowed to quit her bed and walk on crutches. Soon afterwards, however, she was seized with violent pain in the knee of the same side, which was more acute at night. She continued much in the same state up to the time of her admission into the infirmary. It now occurred to me that the local symptoms might have originated in the presence of a foreign body imbedded in the soft parts, and that it might be a needle, the circumstance of her being employed at the time in needle-work rendering it probable; and on examining the small rounded body (which had undergone some diminution since the improvement in her general health), I thought I could detect a hard pointed substance by the peculiar resistance afforded to the finger. On September 11th, just six weeks from the time of her admission, I made a crucial incision through the integuments about a quarter of an inch in depth, and after a little time succeeded in withdrawing with my forceps a portion of a needle, about an inch and a quarter in length, which had penetrated with the eye foremost. It is scarcely necessary to add that after this the local symptoms subsided. The patient was discharged quite well October 11th. The pain in the knee, in this instance, arose no doubt from the accumulations in the colon, which

* She had been in the house about a fortnight at this time.

were unusually great : in proportion as this organ was relieved, it subsided, and was nearly gone before the needle was removed.

The causes of morbus coxæ may be thus enumerated :—First, local injuries, such as falls, blows, sprains, &c. during the existence of the tubercular diathesis ; second, injuries, more or less remote, acting as an exciting cause whenever the system is predisposed to take on the scrofulous or tuberculous character ; third, rheumatic action ; fourth, external violence, without any predisposing constitutional causes, the latter are the least frequent. Whenever we are called on to treat diseases of the hip-joint, it will be necessary to ascertain the circumstances under which they may have arisen, as the success of our treatment must be mainly dependent thereon. As scrofulous affections of the articulation are by far the most numerous and important, I shall confine myself principally to a consideration of them. Our first endeavour should be, if possible, to ascertain how long the strumous diathesis may have existed : to do this it will be necessary to obtain a minute history of the diseases under which the patient may have suffered from birth up to the time of the appearance of the local disorder. A most careful examination should be next made of the state of the nutritive functions ; the thoracic and abdominal viscera should be attentively examined, and the extent to which they may have suffered duly estimated. In this way we shall be better able to judge of the probable success of our endeavours to arrest the progress of the local malady ; for according to the length of time the constitutional symptoms may have existed, so will be the difficulty in subduing it. If the lungs should happen to be the seat of tubercular deposit to any great extent, or the liver be disorganized ; all our attempts will prove unavailing. The first indication is to remedy the constitutional mischief, and if our efforts are successful in this respect, the relief of the local malady is almost certain. If hepatic congestion (as is commonly the case) be present, the treatment before described should be adopted without delay. In the earlier stage of the disease the patient should be confined to the recumbent posture as long as any

pain exists ; but as soon as it subsides, he should be allowed to get about on crutches, and take exercise in the open air. Long confinement to bed is highly prejudicial to persons suffering from strumous disorders of any kind. The system of rest, in my opinion, has been carried to far too great an extent in chronic affections of the joints generally. Ioduretted and poppy fomentations may be applied over the articulation, or mild ointments of iodine and iodide of potass spread on lint. If there be much heat of the parts, the ioduretted lotions may prove serviceable. The warm salt water bath will also be useful at this time. As the use of counter-irritants, such as moxæ, issues, &c. have been generally recommended at this stage of the disorder, and have so long found favour among surgeons in the treatment of it, I shall take this opportunity of saying something concerning their use. The constant employment of them, and their equally constant failure in arresting the progress of the disease, is strikingly exemplified in the cases received year after year at this infirmary ; and I consider them not only unproductive of benefit, but exceedingly hurtful to the patient, more especially in their latter stages. I have frequently succeeded, by the healing of a moxa, issue, &c. in allaying hectic symptoms that were otherwise unmanageable. When the integuments become distended by the altered condition of the parts, and by suppuration about the joint, the cicatrices frequently slough, or form outlets to the abscess ; or, if this does not happen, they are often highly sensitive, and in this way the sufferings of the individual are frequently enhanced, especially if the case terminates fatally.

In one case I remember to have seen the carious head of the femur protruding through a large opening, that had originally been an issue, placed behind the trochanter. Sometimes all attempts at healing moxæ, &c. are unavailing, and they assume the form of strumous sores, adding to the superficial ulceration that is often present, especially when local depletion (by repeated cuppings and leeches), and counter-irritation, have been carried to a great extent : the parts being thus weakened, are ever more prone to the

ulcerative process. Whenever these applications are used in the vicinity of the joint, during the existence of the tubercular diathesis, it is my firm conviction (based on continued and often-repeated observation) that a serious injury is inflicted, not only in these, but in all other strumous affections of the articulations generally, and that they are only so many additional causes of irritation and suffering to the patient.

If the disease were independent of constitutional causes, we might perhaps hope for relief; but all the while the deposition of tubercular matter is going on, or cartilage, bone, or ligament, are undergoing disorganization, from an altered condition of the nutritive organs, little hope of benefit can be entertained from local measures, unless the constitutional mischief be first remedied. Every endeavour should be used, in the earlier stages of morbus coxæ, to strengthen the patient by all means in our power. A nutritive and stimulant diet should be adopted in combination with the hepatic treatment, and the bowels should be carefully regulated by means of aperients and enemata of warm water, even after the hepatic symptoms have been subdued, as there is a constant tendency to a recurrence of them. Local depletion should be particularly avoided, for the loss of blood even by a few leeches produces a visible effect on the constitution. Scrofulous patients cannot bear the abstraction of blood, for the supply of it to the system is necessarily deficient, from the defective conditions of the assimilative organs. I have just now observed that the patient should be allowed to walk on crutches as soon as pain subsides, and, if not of the adult age, it is of great importance to maintain them of a proper length, for as they wear down, and the growth of the individual advances, they will of course be too short: if no attention is paid to this circumstance, and the patient be allowed to walk on them, the body will be bent forward, and the limb affected acquire a bad position. In my earlier acquaintance with these disorders I was often struck with the peculiar deformity so produced, without being able to account for the cause. The chest is thrown forward, the lumbar vertebrae curved inwards, and the nates protruded. If we are unsuccessful in quelling the ear-

lier symptoms, and the disease proceeds (as will often be the case, despite of our efforts to the contrary) to the suppurative stage, we must endeavour to moderate it by the application of the ointments of iodine and hydriod. of potass, or the iodide of mercury spread on lint, and applied immediately over the parts. We should be careful to avoid iodism, for if it be carried to any great extent it is generally injurious. I have invariably found that opening of the abscess (and this applies to strumous abscesses generally) is prejudicial; it should be allowed to break of itself, the situation forming no exception to the rule. I have frequently tried the various means recommended by authors, more especially the valvular opening, as practised by Mr. Abernethy, but without success*. The patient, if possible, should not be confined to bed, even during the suppurative stage, but should be allowed to take exercise in the open air, either in a carriage, or by walking on crutches, if not productive of much pain. The milder iodine ointments form an excellent application to the superficial ulcers and orifice of the sinuses in the latter stage. A lotion composed of nitric acid and vin. opii, with camphor mixture, forms an excellent application, especially when the sores take on a sloughing action. The following is the formula of the lotion:—

R Acid. Nitrici, ℥xx.; Tinct. Opii, ʒij.;
Mist. Camphoræ, ʒxvj. M. ft. lotio.

Opium itself may be sometimes used in place of vin. opii. The lotion is generally applied by means of charpie, and the edges of the ulcer are carefully supported by thin strips of adhesive plaster. The dressings may be removed once or twice in the day, according to the exigency of the case. A carrot poultice applied over this dressing is often of service, and forms a most comfortable and cleansing application. The carrots should be boiled and pounded to a soft pulp. The extract of conium mixed with a bread poultice produces an excellent effect in some forms of irritable ulcer. The water dressing, as recommended by Mr. Liston, is frequently serviceable. Great attention should be paid (a circum-

* When speaking of lumbar abscess, I shall have occasion to revert more particularly to this subject.

stance too frequently overlooked) to cleanliness of the surrounding integuments, as the comfort of the patient is very essentially promoted by it. The practice (formerly much used) of applying linseed poultices to serofulous sores seems now to be falling into general disuse, and very justly so, for a more improper and uncleanly application can scarcely be devised. Sea-water applied in any way during ulceration is generally injurious, and it is almost impossible to heal wounds whilst the patient is undergoing a course of sea-bathing. Bathing is always hurtful during hectic symptoms. Injections to the sinuses have been used by some surgeons, and I was formerly in the habit of using them myself, but I cannot say that they ever appeared to me beneficial; on the contrary, in two or three instances I remember to have seen sloughing induced by the practice. Nothing is so important to the patients in the latter stages as the emptying of the lower intestines by enemata: for even when we are unable to stay the progress of the local disorder, much suffering may be thus avoided. Aperients are often too weakening: besides which they will not have the desired effect.

Narcotics of every description have been used to allay pain in the treatment of these cases, but for my own part I cannot say that I have found them productive of much benefit. If they are exhibited in large and continued doses, their influence on the general symptoms is commonly hurtful. Formerly the Ext. Conii was extensively used at the infirmary by Dr. Brown, and it may certainly be said to be more useful than most other preparations.

The next and most formidable disease to which the hip-joint is liable is rheumatism: it sometimes attacks serofulous patients, and when this happens it forms a dreadful complication. It is essentially necessary to ascertain if any rheumatic action exists, by a careful inquiry into the case, for the disease runs its course, generally speaking, with more rapidity than strumous affections of the articulation.

Of all internal remedies I have found Iod. of Potass. combined (if there be no fever) with Decoct. of Cinchonæ, the most serviceable: the various preparations of Colchicum are also useful. As

a local application, the ioduretted fomentations are by far the best, and often productive of the greatest relief. It is almost unnecessary to say that the warm salt-water bathing is highly beneficial. I shall hereafter have occasion to speak more particularly of the iodine treatment, and of the effect of sea air, bathing, &c. in these and lumbar affections: and I shall now proceed to a consideration of the symptoms which characterize the latter.

[To be continued.]

ON THE INSERTIONS OF THE STRAIGHT MUSCLES.

To the Editor of the Medical Gazette.

SIR,

IN perusing Mr. Lucas's excellent work, entitled, "A Practical Treatise on the Cure of Strabismus," I was struck with the account he gives of the insertions of the four straight muscles, in the following paragraphs:—

"In the well-proportioned eye of an adult, the centre of the tendon of the superior rectus, and that of the inferior rectus, are at an equal distance from the cornea, viz. four lines; the inner edges of each are about the same distance, whilst the outer edges are considerably more removed, being distant seven lines."

"The centre of the internal rectus muscle is distant from the cornea about three lines, its superior edge is distant four lines, and its inferior edge five lines."

"Contrasted with the tendon of this muscle, that of the external rectus is distant at its centre from the cornea nearly five lines, and its superior and inferior edges are distant nearly six lines."

Mr. Lucas does not say what he means by a line. If he means one-tenth of an inch (see Johnson's Dictionary), his measurements are very inaccurate: less so, if he means one-twelfth of an inch.

I do not pretend to doubt that Mr. Lucas has stated the measurements, in the foregoing paragraphs, after actual examination: but, either from using an inaccurate means of comparison*,

* To those who are in the habit of measuring minute parts of the body, I would recommend a

from having before him at the time a subject in whom the attachments were extraordinarily wide from the cornea, or from some other circumstance which I cannot explain, he has set down distances which certainly do not correspond with the average insertions of the straight muscles. That there are varieties in the distances from the cornea at which these muscles are inserted, is extremely probable: but as I conceive that, by following Mr. Lucas's statements as general rules in performing the operation of myotomy for the

cure of strabismus, the operator might be led to attempt the division too far from the cornea, and thereby render difficult what is, in general, the simplest of all operations. I have again carefully examined the insertions of the straight muscles, and beg leave to state the following measurements from the eyes of an adult male subject now before me.

The differences between Mr. Lucas's measurements and mine will be best exhibited by placing his in one column, and mine in a second.

Rectus internus.

| | | |
|-------------------------------------|-------------|---------------------|
| Insertion of centre of tendon . . . | 3 lines . . | 4-20ths of an inch. |
| —————superior edge of tendon . . | 4 lines . . | 6-20ths .. |
| —————inferior edge of tendon . . | 5 lines . . | 6-20ths .. |

Rectus externus.

| | | |
|-------------------------------------|-------------|------------|
| Insertion of centre of tendon . . . | 5 lines . . | 5-20ths .. |
| —————superior edge of tendon . . | 6 lines . . | 7-20ths .. |
| —————inferior edge of tendon . . | 6 lines . . | 7-20ths .. |

Rectus superior.

| | | |
|-------------------------------------|-------------|------------|
| Insertion of centre of tendon . . . | 4 lines . . | 7-20ths .. |
| —————inner edge of tendon . . . | 4 lines . . | 6-20ths .. |
| —————outer edge of tendon . . . | 7 lines . . | 8-20ths .. |

Rectus inferior.

| | | |
|-------------------------------------|-------------|------------|
| Insertion of centre of tendon . . . | 4 lines . . | 5-20ths .. |
| —————inner edge of tendon . . . | 4 lines . . | 5-20ths .. |
| —————outer edge of tendon . . . | 7 lines . . | 6-20ths .. |

While making the measurements stated in the second of these columns, I noted the following particulars:—

1. The internal and external straight muscles are inserted symmetrically, in the same horizontal line.

2. The superior and inferior straight muscles are not inserted symmetrically, nor in the same vertical line; for the inferior is inserted exactly in the middle line of the eyeball, but the superior is considerably nearer the nose than the middle line of the eyeball.

3. The internal is the thickest and shortest of the straight muscles.

4. The external is the longest of the straight muscles, and is next to the internal in point of thickness.

5. The internal and external straight muscles are inserted concentrically to the edge of the cornea.

6. The inferior straight muscle is not inserted concentrically to the edge of the cornea, and the insertion of the superior is placed still more obliquely to the edge of the cornea. The obli-

quity of the two is not equal, as Mr. Lucas's measurements would indicate.

It is a question of considerable importance, to what degree the straight muscles contract after being divided. Bernoulli* shewed that their greatest contraction, in the motions of the eyes, equalled very nearly one-fifth of their natural length. If this degree of contraction takes place when one of these muscles is divided, the point of re-adhesion to the sclerotic must always be behind the transverse axis of the eyeball, unless previous inflammation of the cellular substance around the muscle prevents it from being retracted to the usual extent.

Mr. Lucas's description of the fasciæ in connection with the muscles of the eyeball is very instructive. I have often thought, however, that a separate bursa mucosa existed beneath the tendons of each of the recti.—I am, sir,

Your obedient servant,
W. MACKENZIE.

Glasgow, March 6, 1841.

comparative scale of the English and French inch, sold by Ross and Co., 33, Regent Street, as a very neat and convenient instrument.

VACCINATION.

To the Editor of the Medical Gazette.

SIR,

IN answer to Mr Crawford's inquiry, whether a person can conscientiously be registered as having been regularly and successfully vaccinated, in whom, out of four incisions made, one only takes effect, and that one is retarded in its normal course by forty-eight hours, Dr. Gregory affirms that he may be registered, and gives as his reasons—1st, that any attempt to reproduce the disease after the lapse of one, two, or three years, will fail, proving that the system has *received* from one vesicle a certain influence which it did not previously possess; and this insensibility to renewed insertions of the vaccine virus I hold to be the only legitimate criterion of perfect vaccination: 2dly, that the retardation of the vesicle does not preclude its legitimate influence on the system: in both of which conclusions I perfectly agree with Dr. Gregory: but with all due submission to so high an authority, I must contend that the reason by which he arrives at his conclusion is false, inasmuch as he asserts that the system *receives* from this one vesicle that influence which protects it from an invasion of variola; whereas, in my humble opinion, the system becomes affected by the absorption of the virus, and the vesicle is the result of its effect on the constitution, enabling it to secrete a specific virus, capable of producing the same disease.

To say, then, that the constitution receives its influence from the vesicle is incorrect reasoning, and liable to produce false views of the disease, in those members of the profession who are apt to take the opinions of talented men for granted, without being at the trouble to think for themselves. To prevent so false an impression is the only object of this communication; as the higher the authority is from which such reasoning comes, the greater necessity there is for its being refuted. This may appear to some members of the profession, perhaps, of little importance; but, on reflection, I think it must be granted that, where any principle of pathology is involved, we cannot be too strict in our reasoning to

enable us to come to a correct and legitimate conclusion.—I am, sir,

Your obedient servant,

THOMAS TAYLOR.

Cricklade, March 22, 1841.

CICERO.

CAMBRIDGE STUDIES.

THE Dean of Ely, as our readers will have learned from our last article, wishes to abolish, as nearly as may be, the system of private tuition in the University of Cambridge. He is so indignant at every thing which resembles cramming, or which tends to destroy the freedom of study in that great seminary, that he would not only prohibit private tutorage by express enactment, but would willingly lessen the temptation to it by diminishing the amount of knowledge required both for honours and the common degree. This is going too far, surely; do not throw away the baby with the bath, say the Germans*; because some are crammed, do not forget that others are taught; and above all, do not diminish the minimum for a B.A. degree, when its increase has already produced the best possible effects. "There is no doubt," says Dr. Peacock, "but that the increased severity of the examinations for degrees has already augmented the amount of study amongst those students of the University whose industry is rather stimulated by their fears than by their ambition and love of knowledge, and that the best effects have been consequent upon this change, both as regards the orderly habits and

* Verscütt' Er nur nicht gar
Das Kindlein sammt dem Bade!
Bürger.

general occupations of a great majority of under-graduates."

This is sufficiently cheering; but as the web of life is ever of a mingled yarn, we can easily conceive that these great advantages have been purchased by some sacrifices, and we sympathize with the Dean, when he laments the consequent decline of attendance on University lectures, and the decreased cultivation of individual tastes in the pursuit of knowledge. Yet, on the whole, the balance is obviously in favour of the new system; and as time moves on, the less brilliant under-graduates will think of the coming examination with less terror, and will find that they have abundant time for attending lectures on history or chemistry.

Dr. Peacock's aversion to the stimulus of private tuition has partly influenced him in proposing another alteration, where we are again compelled to differ from him. Composition in Greek and Latin verse at present always forms a part of the examination for the Classical Tripos; but Dr. Peacock wishes to abolish it. If we were inclined to settle the question by authority, it might be sufficient to observe that this species of composition is cultivated at classical schools in England with a diligence nearly proportioned to the excellence of the school—a rule to which we believe the exceptions are but few. Now, in mechanical language, "action and reaction are equal, and in opposite directions;" and as English schools of the higher class are naturally governed in many points by Cambridge methods, so the University herself does not disdain to be influenced by the customs of the best grammar schools. The ocean, say travellers, is sometimes tinged by the waters of the great rivers which flow into it.

These lesser preliminary Universities

have not given up Latin verse-making but of late years have added Greek. The reason is a simple one. Experience has shown that there is no method of familiarizing the student with the beauties of the ancient writers so certain as that of making him attempt to imitate them. In many instances the attempt is a feeble one, but even then, as in the old fable, though the hoped-for gold is not found, the vineyard is much enriched by the digging. Others are more successful; and though we are far from concurring in the extravagant praises which have sometimes been lavished on these imitations*, it must be acknowledged that they often display surprising ingenuity. It may be urged, indeed, with great truth, that the heights of poetry can be attained only by him who writes in his native tongue, where alone he can be a ποιητής, or creator. Besides the in-born inferiority of professed imitation, it is scarcely possible for the most laborious compiler of a classic cento to avoid errors. If Theophrastus was instantly found out to be a foreigner by the Athenian herb-woman, from the very excess of his atticisms, what faults, what solecisms, would be detected in the compositions of our modern Theophrasti, could some Aristarchus rise from the grave, to prefix the fatal obelus to their lines!

We allow the weight of these observations, and are far from confounding modern Bristol stones with the ancient diamonds; but, at the same time, we are convinced that no better way of cultivating literary taste has been devised than the method in question. Dr. Peacock would continue the translations into Greek and Latin prose, though hostile to those in verse. To

* Cowper thought Vincent Bourne's longs and shorts better than those of several of the best real Latin poets; and Lord Monboddo pronounces Milton's first elegy to be equal to any thing of the "elegiac kind to be found in Ovid, or even in Tibullus." (c)

us it seems that both rest on the same theory, and may be defended by nearly the same arguments, excepting that composition in verse is more spirit-stirring and more improving. Our readers will observe, that we do not enter upon the vexed question of classical education in general, nor attempt to ascertain for what classes of persons other styles of mental discipline might be more advantageous, but confine ourselves simply to the minor point:—granting that a number of years are to be expended on the finest models of literary excellence, how is the spirit of these models to be transfused into the thoughts and language of the student?

We may remark, that the compositions in prose which the Dean approves of, are also much neglected at inferior schools; so that the student who has passed his boyhood at one of these academies will find himself in want of a tutor at Cambridge, if he wishes to be distinguished in classical examinations. And if it should turn out that there are half a dozen schools in England which, though tolerable in other respects, neglect composition in verse, would it not be better that they should rise to the Cambridge level, rather than that the University should sink to theirs?

Dr. Peacock laments the condition of the student who is compelled to imitate so many kinds of ancient poetry: "he must write sapphics, after the manner of Sappho; iambs, and sometimes trochaics and anapæstics, in imitation of the Tragedians and Aristophanes; hexameters, after the model of Homer: whilst, in Latin, he must be able to imitate the lyrical metres of Horace (including his *aleaics*, which no other Latin poet attempted to compose); and the hexameters and elegiacs of Virgil, Ovid, and Tibullus."

Greek sapphics are written in the

contest for Sir Willam Browne's medal; but if they are set in the examinations for the Classical Tripos, we would willingly see them struck off the list; for it requires something almost equal to poetic inspiration to imitate a writer of whom so few fragments have been preserved. It is almost too much to say to any student, but of the highest stamp,

Tu longè sequare, et vestigia semper adora—

when time has left only a few interrupted tracks, and the rest must be supplied by the imagination!

But even if no other ancient poet followed Horace in composing *aleaics*, this metre has been used by so many modern writers, and is so deservedly a favourite, that it would be one of the last to be given up. Milton, Gray*, and Dr. Johnson, are among those who have made the attempt, and it is not uncommon at most of our higher schools.

The Dean of Ely informs us that the introduction of Greek composition into the University of Cambridge took place not more than twenty-five years ago, and that it has lowered the standard of excellence in writing Latin. This may be easily conceived; but is Greek composition therefore unadvisable? Surely not. If we are asked why so few persons can read Greek with any facility or correctness, *ad aperturam libri*, we should answer that, in addition to the extreme difficulty of the language, the chief reasons are, first, the neglect, until a very recent period, of Greek composition; secondly, the use of Greek and Latin, instead of Greek and English Lexicons, together with the scantiness of those of the latter kind; thirdly (which we suggest with diffidence), the custom of perplexing

* Gray's ode, beginning "O tu severi Religio loci," written in the album of the Grande Chartreuse, in Dauphiny, in August 1741, has considerable elegance.

the student with the most exquisite minutiae of grammar and criticism, before he can read an easy author with fluency.

On the subject of professional education, the Dean of Ely offers several suggestions worthy of consideration, and, perhaps, in some points, of adoption.

After remarking that at least one-half of students in the University are designed for the church, he adds that no provision is made for their professional education, except the lectures of the Norrisian professor. By provision, the Dean evidently means compulsory attendance: other theological lectures are given, but the student hears them or not, as he pleases. Nor must we overlook the provision made for theological education of this class of students in common with all other undergraduates, such as the University examinations in the Acts of the Apostles, Paley's Evidences, &c.; and the College examinations in the same or similar subjects. Still, something might be added with advantage. The Dean of Ely proposes that six regular courses of lectures should be given every year, by different professors; two of them by professors to be hereafter appointed, namely, of Biblical Criticism, and Ecclesiastical History. These lectures would generally be attended in the year following the B. A. degree, though they might also be attended by undergraduates. All candidates for holy orders, says Dr. Peacock, should be examined by the several professors, and their joint certificate should replace the present testimonial of the Norrisian professor.

As this alteration would either interrupt the usual course of study, or would entail the expense of an additional year's residence, it is easy to foresee that it will be strongly objected to. We would therefore propose that, in addi-

tion to the present certificate of the Norrisian professor, candidates for orders, at any time after their B. A. degree, should pass an examination in the New Testament in Greek, in Ecclesiastical History, and the doctrines and liturgy of our church. As to medical students, the Dean of Ely proposes what most of them would accept as a boon, a shortening, namely, of the time for obtaining the degree of M.D. This demands caution; and though we do not object to lopping off a year or two, yet, in common with every friend to the University, we should shrink from the thought of its annually sending forth a shoal of young men nominally qualified to teach medicine. Dr. Peacock, however, proposes that the degree of B. A. should always be a preliminary, which would greatly tend to avert such a catastrophe, and maintain the social standing of Cambridge medical graduates*.

Such are a few of the points touched upon by the masterly pen of the Dean of Ely. We have no room to give an account of the Master of Glomery, the nature of whose office is a *crux* to Cambridge antiquaries; nor of "the entering of a master in gramer," a degree not conferred since the year 1543†; nor of many other ancient and curious custom.

Dr. Peacock's book will not be thrown away; for the University of Cambridge is ever ready to stand in the van of educational progress, and to yield to the agreeable necessity of continual improvement.

* Those who wish to know what were the medical studies of Cambridge three centuries ago, may see them detailed in Dr. Peacock's Appendix, p. lii. *note*. Galen was then read in Latin translations from the Arabic.

† "Then shall the Bedell purvey for every master in Gramer a shrewde Boy, whom the master in Gramer shall bete openye in the Scolys, and the master in Gramer shall give the Boy a Grote for his Labour, and another Grote to hym that provyde the Rode and the Palmer, &c. de singulis. And thus endythe the Acte in that Facultye."

From an account drawn up, in the sixteenth century, by Matthew Stokys, M.A. (Dr. Peacock's Appendix, p. xxxvii.)

SURGICAL LETTERS FROM PARIS.

NO. I.

To the Editor of the Medical Gazette.

SIR,

THE following brief notices may not be unacceptable to those of your readers who take an interest in what is going on in the Parisian surgical world.

Your obedient servant,

EDWIN LEE.

Paris, March 1841.

There is but little alteration in the leading features of the surgical practice of Paris since my last visit to its hospitals, though a considerable improvement has taken place in the practice of some individuals. Operations are perhaps as much in vogue as ever, but little having as yet been done with regard to the medical treatment of surgical diseases, in which department English surgeons so greatly excel, and which frequently obviates the necessity of operating. An exception must however be made in favour of M. Lisfranc, who continues to prescribe a variety of internal medicines, and general constitutional treatment, in many local complaints, though his employment of these measures falls very much short of the English practice. M. Velpeau also employs medicines in some cases, though they are mostly exceptional. More attention is, however, now paid to the general treatment after operations and accidents than was formerly the case; patients being much less frequently left with constipated bowels for several successive days, and kept on a rigid diet for a long period after the symptoms of inflammation have subsided, though the ghost of Broussaism still renders practitioners very chary in the use of laxatives, or of solid articles of diet, in these cases. Wounds and stumps are still, as heretofore, loaded with charpie, which prevents their healing as soon as they otherwise might do, and causes abundant suppuration, which not unfrequently gives rise to serious constitutional symptoms. Several amputations of the leg have been, within the last twelve months, performed with success, six or seven inches above the ankle, to enable patients to wear an artificial leg, and obviate the unsightly appearance of a wooden one. Simple fractures are fre-

quently treated by the starched bandages, especially those of the upper extremity; but I have not seen patients walking with crutches about the wards of the Paris hospitals, a few days after fracture of the leg, which they are enabled to do in London by the application of the immovable apparatus; whether starch bandages and pasteboard splints, Amesbury's splints, or the tin ones (as at the North London Hospital,) be employed.

Diseases of the eyes are now much better understood and treated in Paris than a few years ago; which I consider partly owing to M. Sichel, a German by birth, who came to reside in Paris, and established an ophthalmic institution, which students will do well to attend, as they may there see a great variety of these diseases, the peculiarities of which, and the rationale of their treatment (a combination of the German and English methods) are fully explained by M. Sichel, than whom I do not know any one in whose opinion I should be disposed to place more confidence in any doubtful case. While mentioning diseases of the eyes I may notice the operation of extracting capsular cataract by the sclerotic, which has latterly been performed several times by M. Sichel. The last of these operations at which I was present was performed about a fortnight ago. The pupil was obliterated by the opaque membrane, which protruded into the anterior chamber, and adhered strongly to the iris. An incision by puncture, about a line and a half in length, was made with Jager's triangular-shaped knife, through the sclerotic, about three lines from the margin of the cornea, through which a small forceps was introduced into the posterior chamber, and several attempts were made to seize the membrane, which could not be effected, on account of the difficulty of passing one of the branches before it. A considerable portion of the vitreous humour escaped; but its further escape was arrested by closing the eye for a few seconds after each ineffectual attempt. M. Sichel at last succeeded in seizing the membrane, and drew it towards the aperture, though the adhesion was so strong that the iris was separated for some extent from the ciliary ligament, and a small quantity of blood effused. A minute portion of the membrane was,

however, snipped off, and a circular pupil was the result. The after-inflammation was but slight; the remains of the capsule were drawn to the circumference, and a large central pupil existed a few days after the operation, enabling the patient to see very well.

An ingenious speculum has just been invented by M. Charriere, which widely separates the eyelids without pressing upon the globe of the eye, and which would be invaluable in operations on this organ in country practice, as it enables the operator to dispense with an assistant. It consists in an elastic steel semicircular bow, which fixes to the back of the head much in the same way as a truss. Its anterior part is divided into two branches, which, by their elasticity, keep the eyelids separate. It was used a few days ago, for the first time, by M. Guérin, in his operations for strabismus. And this leads me to say a few words respecting this operation, which has been made a handle by some persons to puff themselves in the papers. Thus one individual was said to have been operated upon one day, and his appearance so much altered, that the following evening he mystified his friends at one of the masked balls, without wearing a mask. Another story was circulated of a husband who, wishing to occasion an agreeable surprise to his wife, was operated upon. The lady, however, would not recognize him, and he was obliged to sue for a restitution of conjugal rights. These pitiful attempts, though they may procure the inductors a temporary notoriety, cannot fail to lower them in the estimation of the profession, and ultimately of the public. But to return to the operation, the original suggestion of which is generally considered to be owing to Stromeyer, whom I had the pleasure of meeting at Erlangen last April, and with whom I had a long conversation on the subject of muscular contractions, several cases of which, cured, or in progress of cure, he shewed me. Since that period he has succeeded Graefe at Berlin. M. Guérin, however, states that, in his conferences upon deformities, he suggested this method of remedying squinting before its announcement by Stromeyer, but was deterred from putting it into practice by the dread of serious inflamma-

tion of the eye. Be this as it may, the sub-conjunctival method of Guérin, though somewhat more difficult of performance, appears to me to be attended with less inconvenience, and less risk of inflammation, than the other methods, in which the muscle is exposed for a considerable extent previous to its being divided, or a portion of it cut out, as is practised by Mr. Phillips, and other operators. In the former instance the only inconvenience, in the great majority of cases, is the sanguineous extravasation beneath the conjunctiva and the eyelids, which lasts for several days. The muscle is prevented from reuniting, and consequently the squint from returning, by the simple contrivance of spectacles, with the inner half of the glass, corresponding to the operated eye, rendered opaque by pasting a piece of paper on it: so that the patient, in order to see, is obliged to turn the eye rather outwards. After the latter method of operating a fleshy excrescence is produced after cicatrization, which requires to be excised: inflammation is sometimes severe, and in several instances the muscle attaches itself to the globe of the eye too far back: a degree of divergence from the central line, and consequently double vision, is produced; or, from the attachments of the internal rectus having been so extensively divided, its antagonist draws the eye outwards, and the same result ensues.

An operation was performed by M. Guérin about three weeks ago, for congenital luxation of the thigh, in a girl about twelve years of age, which consisted in dividing the rectus, and the portions of the adductors which were felt to be tense beneath the skin. Traction was subsequently made by attaching to the limb a weight, which passed by means of a pulley over the end of the bed, and a few days afterwards the reduction was effected without the necessity of employing a great deal of force. The circumstances which render reduction applicable in many cases of congenital luxation, even after several years have elapsed, were explained by M. Guérin to the pupils; the muscular contraction being the chief impediment, the ligaments not being ruptured but merely elongated, and the cavity not being obliterated as occurs in luxations which are the result of

violence, and in which an artificial capsule has formed.

An immense crowd was collected at the last sitting of the Académie de Médecine, in expectation of the uproar which took place during the preceding one, on the occasion of M. Amusat presenting some patients who had been cured of stammering by the division of the genio-glossi muscles, when M. Gerdy exclaimed, that people now-a-days performed operations right and left without regard to propriety, and that he saw in these operations little else than mercenary motives. It was, however, decided, in order to prevent a recurrence of the scene, that the patients should be examined by a committee.

In my next letter I will mention some of the more interesting cases which have fallen under my observation within the last few weeks.

CLINICAL LECTURE,

Delivered at University College Hospital.

February 9, 1841,

By SAMUEL COOPER, Esq.

Senior Surgeon to the Hospital, &c.

GENTLEMEN,—It is observed by Scarpa, that the femoral hernia seldom occurs in young girls, and still more rarely in men. Yet I have certainly seen many more instances of it in the latter than the former, and am disposed to suspect that the preceding statement, though coming from a high authority, is somewhat questionable. The following is not the only example of femoral hernia that has been noticed in the male patients in this hospital.

CASE I.—Strangulated femoral hernia in a male subject; operation; gangrene of the bowel; recovery.

Charles Lutwyche, æt. 51, admitted under Mr. Quain, Jan. 30, 1841, about 3 o'clock in the afternoon. Twenty-one years ago he perceived a tumor, "smaller than a nut," in his *left* groin; it gradually increased, but gave him no uneasiness, and had never been reducible. About twelve months since, another tumor having formed on the *right* side, the patient procured a double truss.

He describes this last swelling as having always been easily replaced, but liable to descend again whenever the truss was laid aside. At present there is no tumor on this side. Last night he was laboriously employed in carrying sacks of coal in a gas

manufactory, and this morning, at 9 o'clock, while he had his truss on, he became very unwell, feeling an inclination to vomit, and to go to stool, with pain in the abdomen and in the tumor of the *left* side, which was found to be larger and harder than usual. He went home, and took an ounce of Epsom salts, which was soon followed by a scanty solid motion.

On his admission, he complained of pain over the whole abdomen, which was much distended, tympanitic, and tender on pressure. He experienced continual nausea, was restless and agitated, and occasionally vomited up a greenish fluid. There was no tumor on the right side; but in the left groin was found an oval, tense, painful swelling, about as large as a goose's egg, slightly moveable on its base, which was narrow, and extended transversely. The upper margin of the tumor was concave, and thrown over Poupart's ligament, which could be partially traced beneath it; and, on the other side, the femoral artery was felt pulsating. There was no preternatural heat, nor discolouration. The taxis having been tried without success, the patient was placed in a warm bath; and as soon as collapse and faintness had been thus brought on, the taxis was unavailingly tried again.

At 6 o'clock, Mr. Quain, finding that there was no chance of returning the parts by the taxis, recommended the operation; but this proposal was at first declined. The pulse was now 54, and rather small; the belly more tense and tympanitic; the tongue dry, but clean; the vomiting continuing; but the griping pain less severe. On the principles advocated by Dr. O'Beirne, an œsophagus tube was introduced about two feet up the large intestines, but no flatus escaped; and, consequently, no opportunity was afforded of testing the efficacy of such discharge of air in promoting the success of the taxis.

Passing over some minor circumstances, I will next notice the operation. The hair having been removed, and the integuments held up in a fold, Mr. Quain made an incision across the narrow diameter of the tumor, about three inches long, and directed obliquely inwards, and then another about one inch in length, directed inwards, and joining the first about its centre at a right angle. The sac was then carefully dissected down to, and a piece of it having been lifted up with a pair of forceps, was opened, and the opening enlarged with the aid of a director, whereby a considerable mass of brownish omentum, full of highly congested vessels, was exposed; and on turning this up, some folds of intestine were perceived at the inner side, of a deep and uniform slate colour, and without any visible ramification of vessels. The sac contained no

fluid, and the omentum was adherent to the neck of the sac (a circumstance explaining the irreducible state of the hernia, even from an early period of it); but the intestine itself was quite free from adhesions. Mr. Quain having reached the stricture, which was a remarkably tight one, introduced Sir Astley Cooper's hernia knife, under the guidance of the left fore-finger, and divided the stricture to the extent of a few lines; but finding this insufficient, he made another slight cut. Both incisions were almost directly inwards. He then began to return the intestine, and, whilst doing so, about half an ounce of thin fecal matter escaped into the sac; and, on examining the intestine, an opening was detected in its anterior part, at the distance of an inch and a half from the stricture, about four lines in diameter, and the edges of which were very soft, dark coloured, and irregular. Within a few lines of this opening was also noticed a dark spot of nearly the same size, and evidently in a state of gangrene. Mr. Quain next passed a loop of thread through the sound portion of intestine at each side of the opening, and, with some difficulty, reduced the rest of it, leaving the opening itself in the neck of the sac, where it was retained by means of the loop of thread, the ends of which were tied over a fold of lint. The protruded omentum having been cut off, the wound was simply covered with lint. Soon after the patient had been put to bed, the house-surgeon found it necessary to tie two small omental arteries, and, at this time, during a slight effort made by the patient, a gush of thin serous fluid, slightly tinged with blood, took place from the wound. Lint, wetted with cold water, was now applied.

January 31st, 1 o'clock A.M.—Occasional discharge of the same kind of fluid from the wound, but no return of bleeding. Patient feels easier; belly is less tense, though tender on pressure; no vomiting. Pulse 60.

R Hydr. Chlorid. gr. ij.; Morphine Hydr. Chlor. gr. $\frac{1}{2}$; ft. pil. quaque hora sumenda. Poultices to the abdomen.

8 o'clock A.M.—Has slept since 4 o'clock; is now remarkably easy. Tenderness of abdomen diminished; tongue yet dry, but clean; no vomiting. Pulse 68. Bed-clothes thoroughly wetted with the thin fluid, slightly tinged with blood, discharged from the wound. Some air escaped from the opening in the bowel, and the griping pains which had been occasionally felt were relieved by it. Same means continued.

1 o'clock P.M.—Tenderness of abdomen continues.

Ant. Tart. gr. $\frac{1}{2}$, with the Calomel, every four hours; and sinapism applied to the abdomen.

10 o'clock P.M.—Discharge of fluid from the wound much lessened; belly rather tympanitic, and tender on pressure; pulse 76; disagreeable smell emitted from the wound, and the lint stained with dirty brown matter; bowels not open. To continue the same plan, with eighteen leeches to the hypogastrium, followed by fomentations and poultice.

February 1st.—Has rested well; a free discharge of fecal matter from the wound; pulse 86.

2nd.—Small doses of the hydrarg. cum creta substituted for the pills of Calomel, &c.

3d.—Tenderness of the abdomen diminished. A copious evacuation of fecal matter from the rectum: that from the wound lessened. The loop of thread is withdrawn.

Vespere.—In the early part of the day five or six loose stools, with griping and tenesmus, and some traces of blood in them.

To discontinue the pulv. hydrarg. c. creta, and have an enema of starch mucilage, with 5j. Tinct. Opii, and take $\frac{1}{4}$ gr. of morphia.

From the wound thick green feces discharged.

4th.—Pulse 60. Tongue furred. Bowels moved three times in the night. Tenesmus continues, with tenderness in the umbilical region. Ordered

R Liq. Opii Sedativ. ℥vj.; Aq. Ment. 3ss. ft. haustus 4tis horis sumend. A sinapism to the epigastrium, and fomentations.

Vespere.—Bowels still much relaxed. Pulse 70, and compressible.

Omit. Liq. Opii Sedat. and have

R Pulv. Cretæ Co. c. Opio, ʒj.; Pulv. Catechu, gr. x. 4tis horis.

5th.—Tenesmus and griping relieved; two or three fecal evacuations in the night, principally from the wound. Beef-tea, with wine and milk.

In the evening a considerable discharge of feces from the wound; tenderness of the epigastrium; loss of appetite. Pulse 72, and fuller. Tongue white.

Hirud. xii. ad epigastrium, and omit the powders.

6th.—Feces abundantly discharged from the wound. Patient seems low. No tenesmus, yet frequent inclination to go to stool.

7th.—Generally better. Discharge of feces sometimes from the wound; sometimes from the rectum. Wine with arrowroot.

8th.—A free evacuation this morning per anum. The fecal discharge from the wound lessened.

9th.—Bowels opened three times in the night. Six leeches on epigastrium, for pain in that region. Wound granulating.

10th.—Improving. All tenderness of ab-

domen has ceased. One regular motion, and less fecal discharge from the wound. A mutton-chop allowed.

14th.—Went on well to this date. A good deal of discharge of feces from the wound to-day, and parts around excoriated, which were relieved by being smeared with lard, and latterly bathed with a lotion, composed of oxide of zinc diffused in water.

15th.—An aperient clyster administered.

16th.—This produced a copious evacuation from the large intestines, and much general relief to the patient. One mutton-chop and two ounces of wine daily.

20th.—No blood with the stools, and less discharge of fecal matter from the wound.

24th.—Vegetables prohibited; wine, beef-tea, &c. continued. Going on well.

March 4th.—No fecal discharge from the wound since yesterday evening, and it appears to be healed. Bowels open every day.

5th.—Cicatrization complete, and health good.

REMARKS.—No doubt this case was originally an omental hernia, and complicated at an early period with adhesion of the omentum to the neck of the sac, so as to account for its always having been, as the man described, irreducible. In his laborious employment at the gas manufactory, on the morning specified, a piece of bowel protruded, and the case changed into a strangulated entero-epiplocele. The femoral hernia, though not common in males, is not so rare as Scarpa supposed, but often overlooked on account of its small size. In men, however, of laborious employments, like our patient, whose work consisted in carrying heavy sacks of coals, and who have been long afflicted with such a rupture, the tumor, if not kept up (as this seems not to have admitted of being) will gradually attain a size that must excite the patient's notice; and in the case before us we find that the swelling was, after the addition of the bowel to the contents of the sac, as large as a goose's egg. In women, though the hernia is likewise generally small, examples are to be found in which it occasioned a tumor extending two-thirds of the way down the thigh.

The case at present under consideration at all events cannot fail to make you remember that men are sometimes the subjects of femoral hernia; and that, with reference both to the taxis and the operation with the knife, you will be likely to commit serious and dangerous blunders, unless you make out the true nature of the hernia by careful examination. Now the femoral hernia may always be known by Poupart's ligament being above the neck of the tumor. In an inguinal hernia, the spine of the os pubis is

behind and below this part of the neck of the sac; but in the femoral hernia, it is on the same level, and on the inside of it.

In the particulars of the case before us, Poupart's ligament is mentioned as being perceived to extend over the neck of the tumor, the fundus of which is also described as being thrown up over that ligament, as usually happens when the hernia is of a certain size. The remarkable tightness of the stricture—a circumstance particularly common in the femoral hernia of the male subject—was likewise exemplified in the present instance.

The gangrenous and ruptured conditions of the protruded bowel, as discovered when the hernial sac had been laid open, though discouraging, did not, as you have seen, absolutely preclude the possibility of a favourable termination. Here the adherent and diseased portion of the omentum was removed; but the partially gangrenous bowel, which had burst, not being adherent, and having but a limited opening in it, was reduced, and the burst portion of it kept in the neck of the sac by means of the threads tied over a roll of lint. This was done that the fecal matter might escape outwards, and not pass into the cavity of the peritoneum. Had the bowel been fixed by adhesions to the neck of the sac, then, of course, no ligature would have been necessary, or proper.

The copious discharge of serous fluid from the wound, as related, came, as I need hardly say, from the peritoneal cavity. I have witnessed several instances of the same occurrence.

One point deserving notice in this case was the mildness of the constitutional disturbance, notwithstanding the complication of the hernia with gangrene and rupture of the intestine.

The case also adds another instance to several which have been seen in this hospital, where, under strict and persevering antiphlogistic treatment, and especially under judicious diet, and with proper attention to cleanliness, nature not only saves the patient, under the disadvantages which this man experienced, but prevents the continuance of that loathsome affliction—an artificial anus.

The discharge of serum, and the tenderness of the belly, were regarded as indications of a tendency to inflammation in the peritoneum, and the calomel and other means prescribed were intended to control any increased action in that membrane. The calomel and tartarized antimony, however, were discontinued when signs of gastric irritation began; or when the mucous, and not the serous membrane, appeared to be the seat of disorder.

CASE II.—*Traumatic Tetanus*

Is the most fatal form of the disorder,—that over which the most skilful treatment and the most powerful medicines seem to have but little influence. The proportion of persons, who recover from an attack of it, is exceedingly limited. It may be excited by a wound, an ulcer, or a burn; and is much more rarely cured than idiopathic tetanus.

Edward Hays, æt 37, a robust bricklayer, of intemperate habits, admitted under Mr. Quain, Feb. 19, 1841. A month ago he trod upon a rusty nail, which penetrated the sole of his right foot, immediately below the outer ankle. He went on a few yards, and then took off his shoe, and extracted the nail from the part. Notwithstanding the injury caused a good deal of pain, he continued to work, but in three or four days he was obliged to rest himself, and apply a bread and water poultice. On the following day some purulent matter was discharged from the wound, and he felt great relief from it. At the end of two more days, he found himself able to return to his usual labour, in which, besides living intemperately, he was much exposed, first to frost, and afterwards to rain.

On Friday, Feb. 12, without having been conscious of any premonitory symptoms, or having suffered any uneasiness in the injured foot, he began to feel considerable stiffness and difficulty in moving his jaw, and pain at the back of his neck and in the pharynx. On the same night he slept but little, and on Saturday the rigidity of the jaw and the pain were increased; he was feverish, and his bowels confined.

15th.—Pain and numbness all over him, except in his arms. Able to stand up, but afraid to walk; and, in the course of the day, the muscles of the trunk and lower extremities were seized with spasm, from which, however, those of the arm remained free. The pain was most severe under the sternum, and the paroxysms of spasm came on twice or thrice every hour. If he happened to be standing at the moment of one of these attacks, he was thrown down on his face, the body being violently flexed forwards. He could neither sleep nor put solid food into his mouth, but took some porter and tea.

16th.—Had taken no medicines; spasms more frequent.

17th.—Visited by a medical practitioner, who bled him *ad deliquium*, and gave him some pills, which acted upon his bowels twice. The frequency of the spasms, and the severity of his sufferings, do not appear to have been lessened by the venesection.

On his admission, the 19th February, at ten o'clock A.M. his countenance was expressive of great anxiety and suffering, and

he was covered with profuse perspiration. The paroxysms came on every two or three minutes; but the spasms did not extend to the upper extremities at all, and the disorder had now put on the form of opisthotonos. The paroxysms only lasted for a few seconds, but created such agony, especially in the epigastrium, that the patient screamed out. In the intervals there was no tonic spasm; but any pressure on the abdomen, or any attempt to move, brought on a paroxysm. During the intermissions, however, the jaw was fixed, though not completely closed, and the apex of the tongue could be protruded. Pulse 120, and very feeble; bowels open; feeling of sickness; purplish discolorations in various parts of the lower limbs; respiration somewhat hurried, and laborious.

R Ferri Sesquioxidi, ʒj.; Theriacæ, ʒj.
Omni hora sumend.

Beef-tea ad libitum.

Half-past 11 A.M.—Passed a copious loose dark-coloured motion, of very offensive smell; difficulty in swallowing and speaking.

In the afternoon he had two motions, with which some blood and shreds of lymph were blended; heat about anus, and constant tenesmus; a paroxysm of spasm every second or third minute; pulse 120; debility greater. The medicine and the beef-tea readily taken.

Half-past 2 P.M.—Paroxysms now less frequent, but not less severe. They come on every five or ten minutes; and in the interval the patient doses. Gurgling cough; mucous rattle heard all over the chest, but most loudly on the left side; breathing more difficult; upper extremities cold and clammy, lower tolerably warm; face and trunk warm, but covered with a clammy perspiration; pulse 120, and feeble; little, if any, tonic spasm.

Half-past 3.—Getting weaker; pulse 126; two stools similar to the last.

4 P.M.—Bowels moved twice during the last hour; pulse the same; spasms more violent, but less frequent; no sleep during the intervals; difficulty in swallowing the beef-tea. Oxide of iron continued.

R Camph. gr. iij.; Opii, gr. j. Ft. pil. omn. hora sumend.

Acetate of cantharides applied to upper part of the leg, to raise blister; and after removal of cuticle, six grains of hydrochlorate of mercury to be applied under the water dressing.

Half-past 4 P.M.—The acetate of cantharides failed to produce vesication; trunk and limbs rather cold; and the patient's face, chest, and arms, covered with cold clammy perspiration: great restlessness; bowels moved twice during the last half hour; pulse

132, feeble and irregular; breathing laboured; mucous rattle all over chest; paroxysms the same in force and frequency.

Takes beef-tea frequently; and at his desire some common tea is being made for him.

Half-past 5 P.M. — Attacked with a violent paroxysm of spasms, extending to the upper as well as the lower extremities; and this being soon followed by another, he expired.

Section cadaveris, 65 hours after death. — Membranes of the brain more vascular than usual; the arachnoid somewhat opaque and thickened, and both over and under it a large quantity of transparent serous fluid.

The vessels at the posterior aspect of the spinal cord were enlarged, of a bright scarlet colour, and presented a remarkably tortuous appearance; the vessels on the fore-part of the cord were of a dark colour, and less numerous.

The bronchial tubes contained a large quantity of viscid frothy mucus, and the vessels of the mucous membrane were a good deal congested; the lining of the larynx, pharynx, and trachea, exhibited a highly congested state; but that of the œsophagus was natural in its appearance.

In the stomach was found a quantity of the oxide of iron, very little changed.

The body externally presented the discolorations observed before death: a small black spot near the right heel denoted the point where the nail had entered; but no lesion of any branch of a nerve could be detected, and there was no suppuration or abscess discoverable in the part.

REMARKS. — Some wounds are found to be more likely to occasion tetanus than others. Lacerated and punctured wounds more frequently bring it on than incised ones; and lacerated injuries of the thumb, fingers, or toes, and punctured wounds of the sole of the foot, are well known as having frequently been followed by tetanus. The case before us confirms this observation.

In hydrophobia, a longer interval takes place between the period of the local injury, and that of the commencement of the constitutional disturbance, than in traumatic tetanus. If the latter disorder did not begin within twenty-two or twenty-three days after the occurrence of the wound, our soldiers in Spain were deemed safe from its attack. Difference of climate, however, may make differences in this respect, for in Egypt the 17th day was found, by Larrey, to be the latest of the attack. Our patient, according to the particulars, was probably attacked about the 23d or 24th day after the accidental injury. Tetanus begins either when the wound is healing, healed, or in a

most unfavourable state, foul, or even gangrenous. Our patient affords an example of the puncture having healed up before the disorder commenced.

He died, also, at one of the most usual periods of traumatic tetanus, viz. about the 6th day from its first attack; though you should remember that the disease is sometimes more chronic, and then the patient may live much longer, and has a better chance of recovery. One remarkable feature in our case was the great number of evacuations of bad quality from the bowels: more generally, there is obstinate constipation, requiring croton oil and other powerful cathartics. Abernethy believed that tetanus was intimately connected with a wrong state of the secretions in the digestive canal: the bad quality of the evacuations in this instance would rather give support to his view.

The sesquioxide of iron was tried on this patient; but, as you see, without any evidence of its having even produced a mitigation of the disorder. I have tried it also; but without success. I mention this not to dissuade you from having recourse to it, because it seems to me to deserve further trials, several well-authenticated instances of recovery under its employment being related. This patient came into the hospital, however, too late for a prospect of benefit from any plan. The appearances noticed in the *post-mortem* examination mostly agree with the descriptions given by the generality of careful observers; especially the congested state of the mucous membrane of the pharynx and respiratory tubes, and the enlarged tortuous appearance of the vessels of the spinal cord.

No injury of any branch of the external plantar nerve could be detected in the dissection. I advert to this, as bearing upon the question what would have been the effect produced on the course of the disorder by the division of the posterior tibial nerve behind the inner ankle on the commencement of the attack on the 12th of February; a week before he entered the hospital. This operation has been performed with decided success, as you may learn from the particulars of a case recorded in one of the volumes of the *MEDICAL GAZETTE*. To afford any chance of benefit, however, I believe that very early recourse to this proceeding is essential. It must be done on the tetanic symptoms first shewing themselves. The incisions, sometimes practised round the wound, appear to be undertaken on the same principle, namely, that of cutting off all communication between the injured parts and the centres of the nervous system.

THE HOSPITALS OF METZ.

THE hospitals of Metz do not compose a whole, but preserve the distinctive stamp of their respective foundations, and are not united by that financial bond which constitutes one of the advantages or inconveniences of centralization. The congregation of which St. Vincent de Paul was the creator, and is still the life and soul, manages three *hospices*, namely, the charity and orphan-house, and the hospitals called *Bon Secours* and St. Nicholas. The last one is of a mixed kind, and resembles those which in most of our great provincial towns are called general hospitals, as at Montpellier, Toulouse, &c. St. Nicholas's hospital is at once a retreat for indigent old age, and a medical asylum for the scrofulous, the epileptic, and different incurable affections; foundlings and deserted children are also admitted there. In spite of the order which reigns in this mansion of so many guests, it is impossible to approve of such an arrangement. It is not at Metz alone that we have to lament the extent of such an institution; these immense hospitals are a piece of municipal vanity, when they are not the unwholesome result of buildings successively heaped together by economy or routine.

The *Bon Secours* is the real hospital of Metz, the clinical theatre which from year to year, from season to season, displays the phases of local disease; it is there alone that there is a succession of patients, and that observation can be exercised on fresh objects; but we are sorry to say that it is far from being an institution which should have had the double object of liberal charity, and the progress of the art of healing. It is situated near the ramparts, in a part of the town where the indigent are crowded together; its back looks on the stream of the Moselle, from which it is separated only by a small garden; nor does its internal arrangement compensate for the badness of its position. It cannot hold more than 140—160 beds. When I visited the hospital, however, with my friend, Professor Forget, who was then going the circuit at Metz, as president of medical juries, the number of beds was more than enough, as there were not more than fifty patients in the house; but we learned from the superior sister, that at certain periods of the year, disease increases so suddenly, that it is necessary to refuse admission to a great number of applicants, who are obliged to content themselves with being visited at home and receiving medicines gratuitously. There are two large wards on the ground floor; they are paved, and it must be difficult to warm them in winter. There is the same arrangement on the next floor, with

some additions. Fresh air is easily introduced, and one observes that exquisite cleanliness (*cette coquetterie de lustre et de propreté*) which distinguishes houses entrusted to the rule of female corporations. All the wards are not yet supplied with iron bedsteads, and the space between the beds did not seem to us in proportion to the mass of atmosphere; this inconvenience is increased by enormous pillars, which might be usefully replaced, as at the Val-de-Grâce, by thin cast iron-columns, the slim and elegant supporters of the upper story. In going over the wards we saw venesection performed by one of the sisters; and we learned, not without surprise, that the hospital has neither in-door nor out-door dressers, and that the dressings, as well as the small operations of surgery, are executed by the sisters. There is no house-surgeon; no apothecary; the shop also belongs to the sisters; one of them presides over the composition of diet-drinks, and the preparation of the daily prescriptions. The hospital receives the chief medicines and chemical products from a druggist in the town; and a dexterous and exact sister weighs, doses, combines, mixes, triturates, dissolves, edulcorates, and adds the usual ornament of a label to the daily series of her elaborations. It would be impossible for us not to do justice to the symmetry of the internal arrangements of the laboratory, the cleanliness of the pots and utensils, the brilliant polish of the scales, the spotless white of the linen in the wards, the affectionate attention of the sisters to the patients, and the quickness of their movements round beds where patients were to be dressed; but we confess that all this was unable to reconcile us to a hospital without in or out-door pupils, without apothecaries, without any scientific impulse in the details, without the steady control of a superior jurisdiction. These offices ought not to be confided to female hands: give a house-surgeon to this collection of patients, among whom Science, like the Deity whom their pain invokes, ought to be always present, always attentive; open these wards to the intelligent observation of pupils, who, at a later period, after having received the doctoral stamp, will be to Metz practitioners early familiarized with the morbid forms of the place, and the genius of indigenous disease. The sisters, moreover, have the exclusive right of walking in the only garden of the hospital; it is clear that the patients ought to be admitted to this privilege. We diligently inquired of the superior what was the diet of the house, and both M. Forget and I were convinced that it is insufficient for convalescents, who should be nourished as well by the quality as the quantity of food. This defect, and many

others, (such as the want of particular clothing for the patients) arise from the scantiness of the funds at the command of the governors; indeed, the annual budget of the town will not allow of a complete remedy; yet it cannot be doubted that the more direct and decisive intervention of medical authority in these hospitals would correct some of the errors which prevail there.

The *Bon Secours* is appropriated to town patients; those from the department are admitted only when the communes to which they belong pay for their maintenance. A sad necessity! The gates of a hospital ought to open to suffering, from whatever village or market-town it may have dragged its slow length along. Why ask for a certificate of birth and origin from the man who is about to die? Does charity know the limits of departments, stamp its deeds with the seal of a commune, or select its harvest on a privileged soil? Our fathers built the house of the sick by the side of the house of the Lord, and they called it the *Hôtel Dieu*, consecrating it as a pious and helpful hostelry for all the pains which wend their way, lame and crooked, over this earth. As the gate of the church is open to every devotion, that of the hospital ought to yield to each languid hand which knocks at it. Governors and physicians, suffer all the sick to come to you, as our Divine Master suffered all children: do not the ailing and the weak compose the perpetual childhood of humanity?

A thought occurred to us at Metz which has already been expressed in this journal, and which our pen will never be tired of repeating; a thought which contains in itself a host of reforms and improvements. It is simply this:—let the government take into its hands all the property and income belonging to all the hospitals and *hospices* in France; and let every department have its share in proportion to its general population and its annual contingent of sick poor; and let all these establishments form part of a general system, governed by a uniform statute vivified by a homogeneous administration, and let it be under the parliamentary control of the Chambers.

Once more we announce this wish, which we number among the desiderata of each new year; may it germinate, and fructify; may it one day ascend the tribune, in the person of some honourable man imbued with the real interests of the country; and may a minister, capable of occupying himself with something besides the preservation of his portfolio, embody it in the form of a bill! While waiting for this miracle, let us finish our rapid glance over the medical institutions of Metz.

One of the most useful is the practical school of midwifery of the department. It

is under the direction of Professor Morlanne, who, with two colleagues, bears the burden of teaching. There is a course of midwifery, and a *clinique* for the diseases of children, and of women in childbed; and gratuitous advice is given daily to town and country patients. This advantage seems to be appreciated, for last year no less than 1423 persons applied for advice. The *Hospice de la Maternité* is distinct from the *Ecole d'Accouchement*. It was founded in 1334, by a citizen of Metz, named Jean La Hungre, for poor pregnant women; and the deed was confirmed in 1337, by the bulls of Pope Clement VI. The sisters of St. Felicity attend in the house, and, which seems strange for nuns, are both midwives and nurses.

Besides these public institutions, Metz affords other relief to the poor. The Sisters of St. Christian, whose chief residence is in this town, and who pass their novitiate here, devote themselves to the sick, and to the instruction of the poor. Their assistance is sought by the sick of every sect, which is the finest panegyric that can be given them.

The municipal board of charity has divided the town into five sections, and gratuitous advice with home visiting are to be found in each. With an honourable solicitude, the physicians of Metz share among them this domain, where science meets religion in order to bring living streams into a withered land, and in the same beings to revivify the body which decays, and the soul which degenerates.

There is an Israelite Hospital, established by a royal ordinance of May 5th, 1832; it contains only eleven beds.

The midwifery school is of secondary rank, and is intended for midwives alone.

For science, there is a military hospital of instruction, and a medical society. The latter participates in the lot of all provincial academical associations; there are alternations of languor and life; and years of silence and of death are followed by a sign of life in the shape of a volume. The Metz society has lately published a volume, and I arrived just in time to receive it from the skilful and learned Dr. Maréchal. Some day I shall return to it, as it contains several interesting papers; in particular, a very good report on the epidemic cholera at Metz. The book has a tendency to usefulness which I will not pass over, and is especially occupied with questions of public hygiene as applied to the city of Metz. This society has been engaged with the useful, while so many others are like the astrologer in the fable.

The hospital of instruction is, without doubt, the true representative of the medical science of Metz, from the scale on which it teaches, from the merit of the men who

have successively directed it, from the extent of the practical theatre which the art possesses there, and from the influence which it exercises over a body of pupils frequently renewed, and many of whom have taken a distinguished rank in civil and military medicine. The hospital of instruction has, moreover, had the honourable privilege of furnishing the town with its favourite practitioners. There is not an inhabitant of Metz who does not pronounce with respect and gratitude the names of Gorsy, Marchand, Rampon, Moizin, and Wullaume; the military hospital has supplied the Institute with an eminent chemist—Serullas; and has given two inspectors to the Army medical board—MM. Moizin and Brault. M. Bégin, now first surgeon at the Val-de-Grâce, belonged to this hard-working school; Boisseau, author of the "*Pyréologie Physiologique*," died there; it has just sent M. Scoulletten, author of the *methode ovariaire* to the Strasbourg Hospital; and a number of other remarkable persons belonging to the Metz hospital of instruction. The distinguished men who now conduct it are unable to reap all the fruit of this long-enduring reputation, or to maintain the dignity of the institution against the injustice of the military spirit which rules at Metz, and casts its shade over every sort of merit which is not expressed by a big epaulette. Fortunately, science escapes from garrison influence, and moves at ease in a vast and handsome establishment capable of holding 900 patients; and fortunately, the *officiers de santé* of the army, and the body of teachers at their head, have never sought for the springs of their emulation and their zeal anywhere but in themselves*.

CASES FROM THE DANISH MEDICAL REPORTS.

DR. RHODE, of Friedensburg, reports—

1. *An interesting case of scrofula treated with iodine.*—A young lady, of twenty-three, in consequence of a fall on the trachea in her twelfth year, had a swelling there, which was immediately pronounced to be strumous, and had gradually increased until she came under Dr. Rhode's care. It extended from the posterior edge of the sterno-cleido-mastoides on one side of the neck, to the same situation on the other, and from above downwards from the submental region to the upper paries of the sternum. The treatment consisted in the exhibition of burnt sponge, ointment of the hydriodate of potash, tincture of iodine, and afterwards puncturing the tumor. Great advantage was derived from these measures.

* Abridged from an article by M. Michel Lévy, in the *Gazette Médicale* of February 6, 1841.

2. *Internal abscess opening into the intestinal canal.*—A countrywoman, aged thirty, four days after recovering from an attack of sporadic cholera, was seized with suppression of urine, and pain in the abdomen, which were followed by a swelling between the umbilicus and the symphysis pubis, a little towards the left side. The case was terminated, and a cure effected, by evacuations of foetid yellow pus by stool.

Remarkable case of secondary syphilis.—A man, who had previously suffered from secondary syphilis, for which he had taken a strong decoction of sarsaparilla and hemlock pills, a year after this treatment, (no secondary symptoms having occurred during the interval.) was suddenly seized with strabismus, without any known cause; and it gradually reached such a pitch, that both pupils were strongly turned towards the nose, whenever he wanted to look either at a distant or near object. As he had previously suffered from caries of the external bones of the nose, I was afraid that a similar disease might have arisen in the orbital bones; and that caries or exostosis in the orbit produced the phenomenon by pressure on the nerves of the eye. As the patient refused to go through a course of sarsaparilla again, on account of his occupations, I prescribed pills of corrosive sublimate, beginning with one-tenth of a grain a day; and at the same time I placed an antimonial plaster on the back of his neck. When about three grains of the sublimate had been taken, the strabismus disappeared; it was succeeded by unquenchable thirst, and a total cessation of the secretion of the skin. The pulse became quick, evacuations by stool were difficult, unfrequent, and clayey; the patient lost his appetite, and the quantity of urine increased so much, that thirty ounces were usually evacuated in a night. The urine was as clear as water, and without odour, deposited no sediment, and, as appeared by chemical analysis, contained no sugar. Hence it was a case of diabetes insipidus, which had, perhaps, arisen from taking cold. Sudorifics, and milk of sulphur to keep the body open, soon removed these symptoms, and the patient, who was rather attenuated, recovered entirely, and is now quite well.—*Zeitschrift für die gesammte Medicin*, from the extracts made by Professor Otto, of Copenhagen, from the Official Reports sent to the College of Health.

"A TRADING CORPORATION."

To the Editor of the Medical Gazette.

SIR,

MY attention has long been directed to the all-absorbing topic of "Medical Reform,"

and I have been much struck by observing in nearly all the communications on that subject, the just meed of praise that is given to the Society of Apothecaries for the gradual, cautious, but consistent mode in which they have advanced the education of the medical student, and thereby raised the character of the apothecary or general practitioner; yet with all this praise there is uniformly mixed up the dreadful charge of their being a trading corporation, and the disgrace that is incurred by the profession in having the conduct of the education and examination of the apothecary entrusted to a "trading body." Now any indifferent person hearing this accusation would be led to suppose that the Society of Apothecaries was composed of a set of petty dealers, and that the apothecary himself was a person too dignified to sell or buy anything. I have carefully examined the list of the members of the Society, and find among them names of men not altogether unknown to science, and some indeed even distinguished in several departments of medical knowledge. But in this highly aristocratic country, I am well aware that the imputation of "trading" is most offensive; yet it appears to me rather strange that the Society of Apothecaries should be reproached for doing that in their collective capacity, which each apothecary individually is anxious to do; for I conceive that as soon as the tyro has passed his examination, he is most anxious to dispose of as much rhubarb and jalap as he can persuade the public to swallow.

I am old enough to recollect the first agitation of the Apothecaries' Act in 1814: at that time it was first offered to the College of Physicians, but they declined to have any connection with the administration of an Act to regulate the education of the apothecary, conceiving that beneath their dignity; in like manner the College of Surgeons repudiated the measure, being, as they said, the "conservators of pure surgery;" but now that the Society, by their judicious regulations and strict examinations, have created a body of many thousands of efficient practitioners, the members of the two learned Colleges can boldly assert, or slyly insinuate, that it is degrading to entrust the education and examination of the medical practitioner to a "trading body." It is a cry that has been raised by some interested individuals, and to serve their own purposes, and is taken up and echoed by those who never allow themselves to think upon any subject, but follow servilely the track that others have made.

GILES JALAP.

March 24, 1841.

THE COLLEGE OF PHYSICIANS.

To the Editor of the Medical Gazette.

SIR,

I HAVE seen a document in which it is proposed that the Royal College of Physicians of London shall admit indiscriminately to their license, without examination, but on payment of "fees," the medical graduates of the British Universities at large, being twenty-six years of age. Now, conceding as I do, that there might be reasons for the admission of practitioners of known character and professional skill, without being "put through the mill," I beg leave to remark as to the sweeping measure proposed:—

1st, That if practitioners of immoral, unprofessional, or even unknown characters, or imperfectly qualified, be contained among the class of persons contemplated, a voucher from a college, constituted for such purposes as the Royal College of Physicians, and formed of members acting on oath, that such practitioners are trustworthy, would, to say the least, be a most monstrous proceeding.

2dly, That if there has been such a strict performance of duty in the medical department of the English and Scotch universities, as to render their existing degrees sufficient passports to the license of the College of Physicians, without further examination, and to public confidence, there can be no use in the College as a controlling authority. Far less would the legislature be justified in increasing its powers, or extending its jurisdiction, as recommended. Such a measure might benefit the College and its new licentiates, but it would not be serviceable to the public, or just towards future graduates of the immaculate universities in England and Scotland.

The advocates of this (what they are pleased to term) "reform," must choose, then, between the horns of a dilemma. If the after-mentioned universities have failed in their duty, would a college, vouching on oath for its due performance heretofore, be the most eligible institution to entrust with new and extensive powers? If, on the other hand, the universities have acted well, why distrust them hereafter, or do any thing but give them full scope?

There is no analogy, in the Apothecaries' Act of 1815, for the plan. The act saved existing rights, but gave no one what he had not before, or any thing but mere immunity. Existing practitioners were enabled, as previously to the act, to practise without incurring farther penalty; but they were not palmed on the public as licentiates of the Apothecaries' Company. If, then, there are to be new penal powers, ex-

empt existing practitioners from the influence of such; but do not buy their co-operation by giving them a false name.

I am, sir,

Your obedient servant,
A PROFESSOR IN THE SCHOOL OF
PHYSIC IN IRELAND.

Dublin, March 1841.

ANSWER TO DR. BUCHANAN'S LETTER ON HIS COMPOUND CATHETER.

To the Editor of the Medical Gazette.

SIR,

I WAS not a little surprised on reading in the last number of your publication a letter from Dr. Buchanan, of Glasgow, in which that gentleman boldly claims the honour of inventing twenty long years since the improved catheter which I introduced to the notice of the profession in your journal of the 22d of January last.

Now, after allowing the Doctor all the honour justly due to his age and experience from one so young in the profession as myself, I feel bound to set the public right, and to show them that I never saw the Doctor's instrument, or heard of it from any "catheter-maker," who "called upon him from England." The design originated in my own mind a few months ago, when witnessing the agony which patients endured from the delay arising from the use of the common catheter. The Doctor says my instrument is in all essential respects identical with his own; this I beg leave to affirm is not the case; and to prove this, I entreat your readers to compare the drawings of both instruments.

Dr. Buchanan, in laying claim to my invention, displays a vast deal of erudition, and clearly shows that he has travelled much farther north than I, who have never visited Scotland. The Doctor allows that "it is quite possible that the same principle may occur to the minds of two different individuals without any communication;" and continues still smoothing me over by allowing that the instrument will prove "a highly useful one." All this is done merely with a view of attempting to gull the public into a belief that nothing good or useful in medical science can be invented out of the precincts of Edinburgh or Glasgow. That the Doctor is attempting to make this impression upon your readers is self-evident; but like many of his boasting forerunners of Scotia, he will only excite the risible faculties of all men of sense, whilst "out of his own mouth" he condemns himself and shows his motive. Hear the learned Doctor: "it is quite possible that the same principle may

occur to the minds of two individuals;" but hear him again: he hopes that Mr. Foulkes, and every other man who takes the trouble to invent instruments, will allow what he (the Doctor) is now labouring so hard to establish, "that *I did invent* the said instrument about the year 1822."

I am not going to assert that Dr. Buchanan did not invent a compound catheter in that year; but I am bound to ask, where did he place the record of his useful invention? in the medical or other public journals? No; but, as he tells us in his letter in your last Gazette, in his *Note Book*;" and this, forsooth, not in the year 1822, but in 1831, when he got one of the instruments constructed.

Now, with all due deference to the Doctor, I think, sir, if he really had invented an instrument possessing any of those qualities which would relieve his fellow men labouring under the direful effects of stricture, he should not have been so selfish as to withhold it for years from the profession; but have acted with the same candour as myself, and the moment he proved its utility given publicity to it. Trusting you will insert this explanatory letter,

I remain, sir,

Yours most respectfully,

JOHN CREXTON FOULKES.

7, Great Homer Street, Liverpool,

LONDON DISPENSARY.

CASE OF CHRONIC LARYNGITIS, WITH PERTUSSIS, IN A PATIENT *ÆT.* 49.

To the Editor of the Medical Gazette.

SIR,

THE peculiarity of the following case consists in the occurrence of a distinct and prolonged crowing noise, the whoop of whooping-cough, in a patient aged forty-nine, during violent paroxysms of coughing. So great was the resemblance, in the present instance, to whooping-cough in a child, that one of the medical officers of the dispensary, who heard the cough from another room, thought I was prescribing for a child affected with whooping-cough, instead of an adult.

Your obedient servant,

C. J. C. ALDIS, M.D.

Physician to the London Dispensary.
13, Old Burlington Street,
March 1, 1841.

Elizabeth A., *æt.* forty-nine, widow, housekeeper. Admitted Feb. 25, 1841. Pulse 72; skin natural; tongue very red at the edges and tip, furred at the base; bowels regular; urine free; catamenia regular.

Hoarseness of the voice, which is some-

times reduced to a whisper; occasionally natural sounds are produced; slight tenderness about the larynx. States that she is subject to violent paroxysms of cough, "like the hoop of a child, only louder." Tightness of the chest, and very scanty expectoration. The "hoop" produces vomiting if it commences after taking food. Is not troubled by the cough at night; sleeps pretty well. Hæmoptysis on Monday last, when she expectorated a dessert-spoonful of dark-coloured blood. There is dulness on percussion at the upper part of both sides of the chest.

Ailing twelve months. The present hoarseness since Tuesday week, but is subject to it "every cold she takes," as well as the "whoop." Has lost much flesh. Has taken "cough pills and opening medicine."

Having heard the paroxysm of coughing, I am able to state that it consists of a succession of expirations, interrupted occasionally by loud whooping, until the patient is nearly exhausted.

TESTIMONIAL.

MR. RICHARDSON, the eminent medical practitioner of Harrogate, having, after the arduous services of fifty years, resigned his practice to Dr. Kennion, it was lately resolved, at a meeting of his friends, to commence a subscription, for the purpose of placing a portrait of Mr. Richardson in the Harrogate Bath Hospital, from which portrait an engraving is to be taken for the individual gratification of the subscribers. Mr. Richardson's numerous medical friends throughout the country will learn with pleasure that the subscription amounts to about £200; each subscription being limited to two guineas.

LECTURES ON THE PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

By DR. WATSON.

LECTURE XXVIII.

Inflammatory and structural diseases of the spinal cord, continued. Treatment.

Apoplexy. Its general symptoms and diagnosis. Different forms of the attack. Predisposition to apoplexy—natural, and accidental. Precursory symptoms.

ALLOW me to repeat that the structural diseases of the spinal cord will most clearly reveal themselves, by their symptoms, to him who most distinctly perceives, and most accurately bears in mind, the *physiology* of that part of the nervous system. But to the best informed, and the most sagacious, they are too frequently obscure and perplexing.

Disease occupying a portion only of the cord, but affecting the *whole thickness* of that portion, from centre to circumference, will be likely to disturb, or suspend, the functions of sensation and voluntary motion in all the parts supplied with motor or sentient nerves by that portion of the cord, and by the portion beyond it. So that a great variety of symptoms depend, when the *amount* of disease is the same, upon the *place* of the disease. A total interruption of the conducting function of the cord, in the neck, above the origin of the phrenic nerves, extinguishes life by stopping the actions of respiration. A similar interruption in the cervical part of the cord, above the origin of the intercostals, but below the origin of the phrenic nerves, destroys life as certainly, but not so rapidly, nor in exactly the same manner. We find the lungs loaded with frothy

serous fluid in such cases; we find the bladder inflamed; and, often, sloughing of the integuments and muscles of the nates and hips. A similar interruption below the dorsal vertebrae is not *necessarily* fatal, even when it is attended with permanent paralysis: but it *usually* is so, sooner or later.

It is commonly believed that disease affecting the *anterior* columns only of the cord, will be likely to disturb, or to suspend, the *power of voluntary motion* in the corresponding parts; to produce *spasm* or *palsy*: and that disease affecting the *posterior* columns alone will be likely to alter or abolish the *faculty of sensation* in the corresponding parts; to cause *pain*, *tingling*, *numbness*, or *complete anæsthesia*. But I have mentioned certain facts which contravene this opinion. Suspend your judgment respecting it. Neither the minute anatomy nor the physiology belonging to the question are yet conclusively settled.

There seems no reason to doubt that disease affecting the *lateral* half only of the cord will be likely to derange *both* the sensibility and the power of movement, in the corresponding parts on the *same side of the body alone*.

If you impress upon your recollection the facts thus summarily stated, you will find in them, I think, a key to many of the phenomena which accompany, and denote, more or less plainly, disease of the spinal marrow.

Inflammation of the *membranes* of the spine is most apt to declare itself by *pain*, increased on motion, of the spine and of the limbs; and by *rigidity* and *spasm* of the muscles of the neck and back. Inflammation of the *cord* itself, which readily passes into, or rather produces, softening of its substance, is most commonly marked, first, with convulsive movements of some parts of the body; secondly, by palsy of those parts, with or without anæsthesia. The same may be said of *suppuration* when it occurs as an event of inflammation; and the pus may be collected

into an abscess in the nervous matter of the cord, or it may be diffused and mixed with softening.

Now I need not dwell upon the *treatment* proper to be adopted in inflammation of the spinal cord and its membranes. *Mutatis mutandis*, it is the treatment already recommended in inflammation of the *brain and its membranes*. When the inflammation is acute, we must take blood freely; from the arm, or by cupping glasses along the sides of the spine. Blood enough may be taken by cupping along this tract to produce the effect of general bleeding as well as of local. Perfect rest in the horizontal posture must be strictly enjoined. Mercury will generally be proper.

In more chronic forms of inflammation within the spinal canal, we still have a capital remedy in cupping; and counter-irritation in various ways, but more especially by means of issues made on one or both sides of the spinous ridge, is also, in many cases, of most essential and unquestionable service.

Great care must be taken, when there is palsy of the bladder, not only (as I admonished you in the last lecture) that the urine be regularly drawn off, but also that the patient be kept *dry and clean*: for if great attention be not paid to this point, sores will form where the urine remains in contact with the skin, to the great increase of his suffering and of his danger. Indeed, take what pains we may, there is always a strong disposition to the formation of sloughs upon the sacrum and hips in cases of paraplegia. They result from the perpetual pressure made upon those projecting points; from the feeble state of the circulation in the palsied parts; and (often) from the irritation of the urine and feces, which are passed without the patient's consciousness.

When the patient is kept clean and dry, and the surfaces on which the weight of his body has been supported begin to be red or angry, you may protect them by a plaster: or by rubbing them with brandy you may sometimes prevent the skin from breaking: or, what is best of all, you may put your patient upon one of Dr. Arnott's hydrostatic beds; and then the pressure will be equally distributed over all that portion of the body which comes in contact with the waterproof material of the bed.

To bring this outline of the diseased states of the spinal cord up to that point in which we left those of the encephalon, I may state that, like the brain, the spinal marrow may become hardened by chronic inflammation; and, like the brain, it may be encroached upon by tumors; fibrous, scrofulous, or malignant. With respect to these, all that I can now say likely to be of any practical benefit to you, is that the symptoms they occasion are those of slowly increasing paralysis,

without fever or what is called reaction; and that the locality, and extent, and effects of the paralysis, will vary according to the part of the cord in which these changes occur, and the depth to which they affect it.

Apoplexy.—I proceed, in the next place, to a perfectly distinct class of diseases of the brain and spinal cord; to the apoplectic affections: and especially to cerebral hæmorrhage, and spinal hæmorrhage.

When a person falls down suddenly, and lies without sense or motion, except that his pulse goes on beating, and his breathing continues, he is said to have been attacked with *apoplexy*. He appears to be in a deep sleep: but this is not all, for you cannot awaken him by the same measures which would rouse a healthy man. He is not in a state of syncope, for his pulse beats, perhaps with unnatural force; and often his face, instead of being pale, is flushed and turgid; and his respiration goes on, though it may be laboured and stertorous. What I now denominate apoplexy, is the very same state which has so frequently been mentioned already in these lectures: it is *coma* occurring suddenly, or coming on (at least) with rapidity. What is coma? it is that condition in which the functions of animal life are suspended, with the exception of the mixed function of respiration; while the functions of organic life, and especially of the circulation, continue in action. There is neither thought, nor the power of voluntary motion, nor sensation. But the pulmonary branches of the par vagum continue to excite, through the medulla oblongata, the involuntary movements of the thorax. When this upper part of the cranio-spinal axis becomes involved in the disease, and its reflex power ceases, the breathing ceases also, and the patient is presently dead.

It is a common question—how would you distinguish apoplexy from the effects of a narcotic poison? If you were summoned to a person in the state I have been describing, how could you tell whether he was affected with apoplexy, or labouring under the influence of a large dose of opium, or merely dead-drunk? Why, so far as the condition of the cerebral functions is concerned, you cannot discriminate the one from the other. In each case there is profound coma; but the cause of the coma is different in each, and you must seek to ascertain that cause in the history and other circumstances of the patient: you enquire whether he is known to have been drinking, you try whether you can perceive the odour of spirits, or of wine, in his breath; or you endeavour to make out whether he has been low-spirited, or in known difficulties; in short, whether it is likely that he may have swallowed poison. But from the actual condition of his

sensorial functions, you cannot solve the question.

Yet let me say, thus in the outset of our remarks upon apoplexy, that it is often of great importance that the diagnosis should be determined. A man was found lying in Smithfield in a state of total insensibility, except that he still breathed. He was carried into St. Bartholomew's Hospital. The house-surgeon thought he smelt the smell of gin in his mouth; and thereupon very properly made use of the stomach-pump: by means of it he discharged a large quantity of ardent spirit; and in the course of a few minutes the man revived, shook his ears, and walked off. If the gin had been suffered to remain in his stomach, and if the remedies of apoplexy had been vigorously put in force, the absorption of the poison would have been thereby accelerated; and the debauch would probably have had a fatal termination. The same remarks apply still more urgently to the case in which opium, or any other strong narcotic poison, is lying in the stomach. Even when there is no great danger, either in the person's state, or in the remedies used for it, it is not a very pleasant or creditable thing to make a false point of this kind. If we do err, however, we had better err on the safe side. The father of the late Professor James Gregory, of Edinburgh (who used to relate the case in his lectures) was once called out very late in the evening to visit an old gentleman of that place. He found him in a completely comatose condition; his wife crying, and his household all plunged in grief and distress. They told him that the patient, whom he now saw in a fit, had come home, and upon the servant's opening the door to him, had fallen into the passage, on his back, in a state of insensibility. Dr. Gregory learned, however, that he had been at the "Club," and he knew well enough that this Club was composed of jovial spirits, fond of their cups; although the gentleman's wife did not know as much. Therefore he ventured to express his "hopes" to the wife that her husband was drunk: a charitable view of the case, at which she was extremely affronted and indignant. He persisted, however, in his opinion, and not long afterwards the patient began to recover his senses. It turned out that he had partaken more liberally than the rest of the Club, and was the *first* to be drunk. Two of his companions carried him home quite incapable of motion: but not liking to introduce him themselves to his wife in that predicament, they placed him with his back against the door, rang the bell, and walked away. Of course when the servant came to open the door, his master tumbled senseless on the floor. I need not point out to you the ridicule which the physician would have brought upon himself, and the damage he might have

inflicted upon his patient, had he busily applied, in this case, the ordinary remedies of apoplexy.

The state of coma, such as I have described as being characteristic of apoplexy, may terminate in one of three ways. It may cease, more or less rapidly, and leave the patient in perfect health. What is the exact condition of the encephalon during the continuance of the coma, in such cases, no one can positively tell. But the occurrence of temporary coma, under the influence of a narcotic poison, and the perfect disappearance of the coma as the effects of the drug pass off, teach us that the functions of the brain may be almost totally suspended for a time by causes which do not injure its texture. It is possible that the coma may depend upon that presumed disturbance of the balance of the arterial and venous circulation within the cranium, which I spoke of in a former lecture. It may be that the force and rapidity of the circulation in the cerebral vessels undergo some great alteration. It is still more probable (to my mind) that a temporary stress upon the cerebral blood-vessels (produced by a determination of blood towards the head, through the arteries, or by a detention of blood in the obstructed veins) may really exercise pressure enough to cause transient coma. But these are mere conjectures.

In the second place, the apoplectic coma may terminate, more or less quickly, in *death*. And on examining the brain we may find a large quantity of extravasated *blood*; or a considerable effusion of *serous fluid* in its ventricles, or beneath the arachnoid; or we may detect *no* deviation whatever from the healthy structure and natural appearance of the organ. The congestive pressure (if it indeed existed) has left no prints of its action.

The last is comparatively rare. Dr. Abercrombie has given to this form of apoplexy, which destroys life, but leaves no traces behind it, the name of *simple apoplexy*. And this name, for its convenience, I shall retain. Of the other two kinds of quickly fatal apoplexy, that in which *blood* is found extravasated is more common than that in which there is effusion of *serum* only. The one has been called *sanguineous apoplexy*; a better term is *cerebral hæmorrhage*: the other has been called *serous apoplexy*.

Thirdly, the apoplectic coma may terminate in *partial* or *imperfect* recovery. One, or all, of the cerebral functions may be left impaired; the mind enfeebled; the power of motion limited, or lost, in some parts of the frame; the faculty of sensation benumbed or extinguished: the unhappy subject of the attack remaining more or less crippled in body, and more or less maimed in intellect. In these cases, when at length we have an opportunity of examining the brain, we al-

most ways find that there has been extravasation of blood, to a small or moderate extent. I say *almost* always, because I have myself, in more than one instance, carefully looked for such appearances, after such a series of symptoms, without finding them. Occasionally, instead of a clot of blood, we meet with circumscribed softening of the brain.

Modes of attack.—The *attack* of apoplexy does not always occur in the same manner: and Dr. Abercrombie has pointed out three several ways in which it is apt to come on. I am confident, from the result of my own observation, that the distinctions laid down by Dr. Abercrombie are just and true; and it is of importance that you should be aware of them. “In the *first* form of the attack, the patient falls down suddenly, deprived of sense and motion, and lies like a person in a deep sleep; his face generally flushed, his breathing stertorous, his pulse full and not frequent, sometimes below the natural standard. In some of these cases convulsions occur; in others rigidity and contraction of the muscles of the limbs, sometimes on one side only.

Now of persons seen in this condition, the immediate prognosis is *uncertain*. Some die in a short time, and much blood is found extravasated within the cranium. Some die after a rather longer interval, and then we often find serous effusion only, and that of no great amount. And in some that die early, no effusion either of blood or of serum can be detected. Some recover altogether, without any ill effect of the attack remaining. Others recover from the coma, but are left paralytic of one side, and with some imperfection of speech, or of one or more of the senses. And this paralysis and imperfection may disappear in a few days, or gradually subside, or remain for life.

In the second form of attack, the coma is not the earliest symptom. The disease generally begins with a sudden attack of pain in the head. The patient becomes pale, faint, and sick, and usually vomits; and sometimes, but not always, falls down in a state of syncope, or resembling syncope, with a bloodless and cold skin, and a feeble pulse. This also is occasionally accompanied by some degree of convulsion. Sometimes he does not fall down, the sudden attack of pain being accompanied only by slight and transient confusion. In either case he commonly recovers in a short time from these symptoms, and is quite sensible, and able to walk; but the headache does not leave him: after a certain interval, which may vary from a few minutes to several hours—and Dr. Abercrombie records cases in which it was even much longer—the patient becomes heavy, forgetful, incoherent, and sinks into coma, from which he

never rises again. In some instances paralysis of one side occurs; but perhaps more often, there is no palsy observed.

The disease, when it comes on in this way, is much more uniform, and of much worse omen, than when it commences after the former fashion. It is of great use to know this; for to an unexperienced eye the cases do not *seem* so terrible as those in which the patient becomes profoundly comatose from the very first. The apparent amendment is fallacious, and apt to lead one into giving a false prognosis. Very few persons come out of the coma, and a large quantity of blood is usually found extravasated in the brain. These cases are not, as Dr. Abercrombie well observes, apoplectic in the outset. They differ remarkably from the first set of cases. If there be at the very beginning some loss of sense or motion, it goes off again in a very few minutes, or perhaps in a few seconds: the prominent symptom, at the commencement, is sudden and violent pain of the head, with faintness, sickness, and often with vomiting. The pain continues, and is sometimes confined to one side of the head; the face is pale and ghastly, the pulse weak, and often frequent or irregular; but the patient is quite conscious, and in full possession of his intellect. At length he recovers his natural temperature, his countenance improves, and the pulse becomes stronger and steadier: then his face gets flushed, he feels oppressed, answers questions slowly, and at last sinks into stupor and fatal coma. The period between the first attack and the commencement of the coma is variable. Sometimes the stupor succeeds the pain and faintness so rapidly, that the case comes greatly to resemble those in which coma is the first symptom, and takes place suddenly; but still a short period of sense, commonly with complaint of great pain, may be observed. But the interval may be a quarter of an hour, or many hours, or even two or three days. “Upon inspection,” says Dr. Abercrombie, “we find none of those varieties and ambiguities, which occur in the apoplectic cases, but uniform and extensive extravasation of blood. [I should state that he calls the first class of cases *apoplectic* cases, the coma being present from the first: and the second class, which we are now considering, he calls cases *not primarily apoplectic*.] The symptoms in this form of attack depend, no doubt, upon the giving way of some one of the cerebral vessels. At the moment when the vessel is ruptured, a shock is given to the brain; a temporary derangement of its functions occurs; but this passes off. The circulation then goes on as before, until such a quantity of blood has escaped from the ruptured vessel as is sufficient to produce coma. There is no part of Dr. Abercrombie’s book more admirable

and clearly put than that which is occupied with these important distinctions, which I give you very much in his own words. He points out the close analogy which exists between this variety of apoplexy, and the result of external injuries, when they occasion extravasation of blood on the surface of the brain. The hurt person recovers from the immediate effects of the accident, walks home perhaps, and after some time becomes stupid, and at last comatose. The surgeon trephines the skull, and discovers blood upon the dura mater; and the blood being removed, the coma goes off. We cannot help our patients by a similar expedient; though the opinion has been broached that trepanning the skull will, at some future period, be a common practice in apoplexy. Dr. Abercrombie conjectures that after the rupture has taken place, the hæmorrhage is sometimes stopped by the formation of a clot at the orifice in the vessel, but at length the blood bursts out again, and proves fatal. He relates two cases in which this probably happened; in one of them an interval of three days, and in the other an interval of a fortnight, elapsed between the first attack, and the supervention of coma. The portions of blood extravasated at the distinct periods may sometimes be distinguished by their appearance—their colour and consistence.

The *third* form of attack is characterized by sudden loss of power on one side of the body, and frequently by loss of speech, without loss of consciousness; or at most with a very temporary suspension of consciousness. The patient is sensible, listens to and comprehends your questions, and answers them as well as he is able, either by words, which in most cases he articulates imperfectly, or by gestures. The farther progress of the cases that commence in this way is marked by considerable variety. Sometimes the hemiplegia passes gradually in a short time into apoplexy. Sometimes the patient soon gets well, the palsy leaving him entirely. Or a gradual recovery takes place, which is not complete for some weeks or months. Or the patient recovers up to a certain point, and there the improvement stops; he regains the power of moving his leg, but it drags somewhat after him; or the leg recovers, but the arm remains feeble, or his speech continues to be inarticulate. And in another variety of this form the patient neither recovers on the one hand, nor becomes apoplectic on the other, but is confined to his bed, paralytic, and perhaps speechless, but in possession of his faculties in other respects, and dies at last worn out and exhausted, some weeks, or months it may be, after the attack. In the outset of these cases there is not always complete hemiplegia, sometimes the arm only is affected, sometimes (but much more rarely) the leg

only. Or some other voluntary muscles are the first to lose their power.

Now the appearances on dissection after death, in cases that have thus commenced (Dr. Abercrombie calls them the class of *paralytic* cases) are, as in the *apoplectic* cases, inconstant. Much the most common of all—according to my own experience—is the extravasation of blood, to a moderate or small amount, and definite extent, in the substance of the brain. But sometimes nothing is found upon dissection to account for the symptoms, or slight serous effusion only. The same symptoms attend some cases of softening of the brain also; or inflammation and its consequences. In a vast majority of cases, I repeat, this sudden hemiplegia marks an attack of cerebral hæmorrhage.

You will not find that all cases of apoplexy commence exactly in the one or the other of the three ways which I have been describing. But most attacks range themselves in one of these classes, and by attending to the points of distinction, I make no doubt that you will often derive much assistance from them in regard to diagnosis and prognosis; and that the distinctions themselves will give a higher interest to your study of this complaint, than it would possess if all the forms of attack were lumped together in one common description.

Predisposition.—In treating of this large subject, this multiform disease, the main points will best be made intelligible by my breaking what I have to say into separate heads. I have told you the different ways in which the disease may make its assault. I will next say something of the persons who are most liable, *ceteris paribus*, to attacks of apoplexy: and afterwards of the symptoms which in many cases, though not in all, precede the seizure, and lead us to fear that it may be impending. It is of great importance to attend to these threatenings; for, as you will readily conceive, the chief good that medicine can do in such cases, is in the way of prevention. After the attack has taken place, the effect of our treatment must be very uncertain. A large effusion of blood upon the brain will be fatal in spite of us: and a smaller amount of extravasation we cannot remove; and the best that the patient can expect in too many cases, is long continued or permanent palsy, a weakening of the mental powers, and sometimes a state nearly approaching to idiocy. Also, when once an apoplectic fit has happened, it is the more likely, on that very account, to happen again. These are quite sufficient reasons why we should not neglect the *warnings*; the symptoms which are apt to precede and herald the attack of apoplexy.

The classes of persons in whom, *ceteris paribus*, attacks of apoplexy are especially to

be apprehended, are those whose *ancestors* have suffered the same disease; those who possess a *particular conformation of body*; and, above all, those who have reached a *certain period of life*. No doubt apoplexy may and does occur in persons whose progenitors have escaped it; in persons of every conceivable conformation; and in persons of all ages. But it is *much more* frequent in the classes I have specified, than it is among persons not comprehended in those classes.

The first and second class sometimes concur, *i. e.* a particular conformation of the body is transmitted from parent to child, and with it is transmitted a proclivity to apoplectic disease. But even when there is nothing peculiar in their bodily form, or in their habits of life, practical men of large experience declare that they who come of an apoplectic stock are themselves more than ordinarily liable to apoplexy.

The pattern of body which is most prone to apoplexy is denoted by a large head and red face, shortness and thickness of the neck, and a short, stout, squat build. This remark is as old as the time of Hippocrates. However, apoplexy is common enough in men and women who are thin, and pale, and tall. *Cæteris paribus*, corpulent people are more in danger of apoplexy than spare people; but it attacks both the one and the other.

Advanced life is certainly a very strong predisposing cause. And the reason of this will be apparent when we come to enquire more particularly into the morbid appearances presented after death by apoplexy. The disease begins to be *common* after 50; but it does sometimes occur even in young children. I am speaking principally of that form of apoplexy which depends upon cerebral hæmorrhage, which is by far the most frequent of all its forms.

Of sixty-three examples of cerebral hæmorrhage collected, and carefully examined by Rochoux, (who has written a very good treatise on this affection), two only happened between the ages of 20 and 30; eight between 30 and 40; seven between 40 and 50; ten between 50 and 60; twenty-three (or more than one-third of the whole) between 60 and 70; twelve between 70 and 80; and one between 80 and 90. To analyze this table a little farther: it appears that of the 63 cases seventeen only took place before 50; forty-six after that age. There are also twice as many victims to the disease between the ages of 60 and 70, as between 70 and 80. And from this fact Rochoux has drawn, I conceive, an erroneous conclusion; and I mention it that, in case his treatise falls in your way, you may not be led by it into what I imagine would be a mistake. There being 23 cases between the ages of 60 and 70, and only 12 between the ages of 70 and 80, Rochoux infers from this

that the disposition to cerebral hæmorrhage *decreases* after the age of 70: which would be a most unaccountable thing, and quite inconsistent with what I believe to be the true pathology of the disease. But I make no doubt that the difference in the actual numbers observed in these two decennial periods depended upon the number of persons alive, at the same time, of the ages of 60 and 70 respectively. There are always more persons living whose age ranges from 60 to 70, than from 70 to 80; and therefore more persons die of apoplexy in the former period. In all probability, if the exact truth could be ascertained, of a *given number* of persons, there are *more* attacked with apoplexy between 70 and 80 than between 60 and 70.

All these three kinds of predisposition are beyond our power. We cannot eradicate the hereditary tendency; nor remodel the plan upon which the body is constructed; nor arrest, or put back, the clockwork of human life: but we may guard and caution persons, thus predisposed by nature towards apoplexy, against many of its exciting causes.

A strong predisposition to apoplexy is, moreover, engendered by certain other diseased conditions; and over some of these conditions our art enables us to exercise more or less control.

Disease of the cerebral blood-vessels is a very common and a very pregnant circumstance of predisposition. I shall revert to this when I describe more particularly the anatomical characters of cerebral hæmorrhage.

Diseases of the chest influence very materially and injuriously the circulation in the head. Without going into detail respecting complaints with which I am obliged to suppose that you are as yet unacquainted, I may state, by anticipation, that impediments to the free transmission of blood through the heart and lungs constitute the mode in which thoracic disorders predispose to apoplexy. The *plethora capitis* produced by such impediments is frequently visible in the turgid and livid features, and in the distended jugular veins.

A very remarkable disease of the kidneys, of which also I must postpone any particular account, renders the system unusually liable to apoplectic affections. I mentioned this renal disease when speaking of the general pathology of dropsy. It is connected, on the one hand, with a morbid state of the urine, which contains albumen, and is deficient in urea; and, on the other, with a morbid state of the blood, which circulates unpurified from the latter excrementitious substance.

The cessation of habitual discharges, of the catamenia, of bleeding piles; he drying up

of old sores; the healing of long established issues and setons; all have an unquestionable tendency, by causing or augmenting plethora, to generate a predisposition to apoplexy.

And large observation of the habits of those who fall victims to this terrible malady, leaves no room for doubting that intemperance often paves the way for its invasion. The continued abuse of ardent spirits, in particular, lays the foundation of many of those morbid conditions of the sanguiferous system, and of the viscera, which constitute the predisposition we are now considering.

Precursory warnings.—Among the *premonitory* symptoms, *headache* is of frequent occurrence: but the same symptom is abundantly common in persons who are in no danger of apoplexy: it derives its minatory character from the concurrent circumstances. Headaches awaken our fears when they *begin* to be troublesome in advanced life. They are, then, still more formidable if they are accompanied by vertigo; or, without any other evidence of gastric derangement, by nausea and retching. Sometimes, as I just now told you, severe headache ushers in, and almost forms a part of, the apoplectic attack.

Vertigo itself, even without headache, is a very common precursor or warning of an approaching seizure. It is sometimes slight and transient; sometimes almost habitual. Although vertigo may depend upon other causes than mischief within the head, we cannot regard it without apprehension when it often occurs in old persons. It should teach us to obviate as entirely as we can all the known exciting causes of apoplexy. The principal of these I shall by-and-by describe to you.

Transient deafness, or transient blindness, blindness or deafness for a few seconds or minutes, is another of these warning symptoms. The late Dr. Gregory, of Edinburgh, used always to mention in his lectures the case of Dr. Adam Ferguson, the celebrated historian, as affording one of the strongest illustrations he ever met with of the benefit that may be derived from timely attention to the avoidance of those circumstances which tend to produce plethora and apoplexy. It is, perhaps, the most striking case of the kind on record. Dr. Ferguson experienced several attacks of temporary blindness some time before he had a stroke of palsy; and he did not take these hints so readily as he should have done. He observed that while he was delivering a lecture, his class, and the papers before him, would disappear, vanish from his sight, and reappear again in a few seconds. He was a man of full habit; at one time corpulent and very ruddy, and, though by no means intemperate, he lived fully. I say he did not attend to these admonitions; and at length, in the sixtieth year of his life, he suffered a decided shock

of paralysis. He recovered, however, and from that period, under the advice of his friend, Dr. Black, became a strict Pythagorean in his diet, eating nothing but vegetables, and drinking only water or milk. He got rid of every paralytic symptom, became even robust and muscular for a man of his time of life, and died in full possession of his mental faculties at the advanced age of ninety-three; upwards of thirty years after his first attack. Sir Walter Scott describes him as having been, "long after his eightieth year, one of the most striking old men it was possible to look at. His firm step and ruddy cheek contrasted agreeably and unexpectedly with his silver locks; and the dress which he usually wore, much resembling that of the Flemish peasant, gave an air of peculiarity to his whole figure. In his conversation, the mixture of original thinking with high moral feeling and extensive learning, his love of country, contempt of luxury, and especially the strong subjection of his passions and feelings to the dominion of his reason, made him, perhaps, the most striking example of the Stoic philosopher which could be seen in modern days."

This anecdote, which I have made use of as a wrapper for some medical instruction, will not be the less acceptable to you when I add that the remarkable man to whom it relates was the great uncle of my friend and present colleague in this school, Dr. Robert Ferguson.

Very frequently slight and partial paralysis is the forerunner of an attack of apoplexy. Double vision is one form in which such limited palsy is apt to shew itself. It is evidently connected with some degree of squinting; *i. e.* some one or more of the muscles that move the eyeball are paralyzed: the person cannot direct each eye to the same object at the same time. This is a very suspicious symptom. Dr. Gregory was acquainted with a sportsman who one day, when out shooting, disputed with his gamekeeper as to the number of dogs they had in the field. He asked how he came to bring so many as eight dogs with him. The servant assured him there were but four; and then the gentleman became at once aware of his situation, mounted his horse, and rode home. He had not been long in the house when he was attacked with apoplexy, and died.

Sometimes the slight and local paralysis shews itself in a faltering or inarticulate mode of speaking. The rapidity of the movements of the tongue requisite for distinct utterance is so great, that the slightest weakness of any one of its muscles is rendered obvious. We see this in one very common form of what may in truth be considered a kind of apoplexy; *viz.* in drunkenness. In many persons the very first symp-

tom of their becoming intoxicated is their inability to speak plainly. "Clipping the King's English" is the slang expression for it; and the same thing often takes place in respect to the more proper forms of apoplexy.

It is a curious circumstance, by the way, and one which is analogous to what we meet with in disease, that different sets of muscles are chiefly affected by intoxication in different persons: the same sets being always the first affected in the same persons. Thus some persons who are drunk lose (as I have just stated) the proper command over the muscles of the tongue, and falter in speech, while they can walk very well: others reel and stagger, having lost, in a greater or less degree, the power of moving and governing their limbs, and of balancing themselves, who yet can speak quite fluently and distinctly; and in a few cases, drunken persons become delirious, who still retain the power of distinct articulation, and of directing their steps aright. This being so, we need the less wonder at the variety in the nature of the warnings that precede the apoplectic attack.

In many cases there is numbness or debility, or total palsy of one limb, or of a single finger, or even of a solitary muscle, as of the levator palpebræ. The patient cannot grasp your hand with firmness, or sign his name in his usual way, or pick up a pin, or snuff a candle, or manage an obstinate button, or tie a knot in a thread cleverly: or, perhaps, one of his eyelids droops, and the eye is half closed. Sometimes, on the contrary, the patient stares at you, frightfully, with one eye, which he cannot shut.

The numbness also assumes various characters, according to its place and degree. One patient will tell you that he feels as if one limb was always muffled in flannel; another, that he is uncertain whether, in walking, his foot has reached the ground or not. One gentleman, since dead of apoplexy, assured me that, when seated, he did not know how far his breech extended beyond the edge of the chair.

All these symptoms are modifications of the function of voluntary motion; or of the function of sensation. Nor are manifestations wanting, among these precursory circumstances, of a derangement of the other and nobler function, of which the brain and nervous system form the material instrument. I mean the function of *thought*.

Thus one very deplorable warning is the loss of *memory*. All persons, I believe, as they grow older, find that they do not retain so tenaciously in their recollection things which have recently occurred, as things which happened when they were young. This depends upon the degree of *attention* which we pay to different circumstances. Those

events which strongly excite the curiosity, and rivet the attention of the boy, become familiar to the man, and he gives them but little notice, and is very apt to forget them. But the loss of memory that threatens apoplexy is something more than this. It is sometimes partial, and extends to certain sets of things only. For example, some persons entirely forget certain words, while they recollect others perfectly. Common words are often thus forgotten, while unusual or remarkable words are remembered: or a wrong word is chosen. One word is used for another that sounds something like it. Thus one of my patients, meaning to accuse a certain individual of *perjury*, always called it *purging*; and many other words he changed after the same fashion. But in truth the modifications of a partial loss of memory that have been known to precede apoplexy are both odd and endless: some people forget their own names, or the names of their children. Dr. Gregory, who had paid particular attention to these precursory symptoms, and who had a large practice for a great number of years to furnish them, used to mention a case of this kind. After some efforts his patient could recall to his recollection what his christian name was, but he could not think of his surname. About twelve months after his memory began to fail in this strange manner he was found dead in his bed. Another gentleman for some time before his death could never recollect the name of the street in which he lived. Upon one occasion of his visiting Edinburgh, he called on Dr. Gregory, and partook of a hearty breakfast, having forgotten that he had breakfasted before he came out. On the same day he attended, with Dr. Gregory, the funeral of a young lady who had been his ward; the funeral took place in the country; and when they returned together in the carriage, the doctor found that his friend had forgotten all that he had been doing. Next day he met him in the street, and saluted him with all the kindness of an old acquaintance at first meeting; saying he was happy to have fallen in with him now that he was in town, and totally forgetful of their former interviews.

Connected with this failure of memory, there is often an unnatural degree of drowsiness. Sometimes, without any other affection of the memory, there is a temporary confusion or suspension of thought: the patient suddenly loses the train of ideas in which his mind had been occupied; stops short in the middle of a sentence, and endeavours in vain to recover the broken thread of his discourse.

Among the mental conditions that bespeak tendency to apoplectic disease, I have several times noticed a strange and vague *dread*, of which the person can give no reasonable ex-

planation; a sense of apprehension and insecurity not accounted for by the apparent state of his general powers and functions; a painful degree of indecision and irritability; with a dislike and fear of being left alone. One patient of mine described his "nervousness" of this kind, by telling me that in descending a staircase, especially a winding one, he was obliged to turn round, and come down backwards, as one descends a ladder; or even to sit down, and so slip, stair by stair, from the top to the bottom. Yet with the assurance given him by a friend's arm, or by a convenient bannister, he could walk down stairs without difficulty. He had no actual vertigo.

I say, all these, and many other signs that indicate a disposition to apoplexy, are well worth your study; because a knowledge of them may enable you to ward off the threatened attack, by medicine, by regimen, and by admonition to the patient on the subject of such exciting causes of the disease as are within his own control. They show that, even before the stroke descends, there is some morbid process going on within the head.

LECTURES ON THE FUNCTIONS OF THE NERVOUS SYSTEM.

By W. B. CARPENTER, M.D.

Lecturer on Physiology in the Bristol Medical School.

LECTURE IV.

Nervous System of Vertebrata.

WHEN we direct our attention to the nervous system of the Vertebrated classes, we are immediately struck by two remarkable differences which its condition presents, from that under which we have seen it to exist in the Invertebrata. In the latter it has seemed but a mere appendage to the rest of the organism,—a mechanism super-added for the purpose of bringing its various parts into more advantageous relation. On the other hand, in the Vertebrata the whole structure appears subservient to it, and designed but to carry its purposes into operation. This is more evident in the higher classes of this group than in the lower; these last bordering, as we shall presently see, upon the classes below. But this gradual weakening of the typical character is common to all natural groups, and indeed marks them to be such; since no group can be regarded as complete, which does not contain *aberrant* forms, by which it is connected with the groups in nearest proximity with it. Between the simple nervous system of the lowest Fishes, and the

highly developed apparatus which is peculiar to Man, we find a most gradual series of transitions, in which no link is wanting.

The second of the conditions above alluded to, is one which gives additional force to the remark first made. In the Invertebrata, we do not find any special adaptation of the organs of support for the protection of the nervous system. It is either inclosed, with the other soft parts of the body, in one general hard tegumentary envelope, as in the Echinodermata and Articulata; or it receives a still more imperfect protection, as in the Mollusca. In the latter, the naked species are destitute of any means of passive resistance, and the nervous system shares the general exposed condition of the whole body; and it is not a little remarkable that, in the testaceous kinds, the portion of the body containing the nervous centres should be protruded beyond the shell, whilst the principal viscera are retained within it. Now, in the Vertebrata, we find a special and complex bony apparatus, adapted in the most perfect manner for the protection of the nervous system; and it is, in fact, the possession of a jointed spinal column which is characteristic of the group. Here, therefore, we exchange the *external* skeleton, formed by the condensation of the integument—the *dermo-skeleton*—for the internal structure composed of true bone, and thus a part of the living tissues, which may be termed the *neuro-skeleton*. The cranium itself may be regarded as only an assemblage of vertebrae, possessing the same constituent parts as those of the back, but having those parts developed in a different proportion. This idea, which, when first propounded, was received with great ridicule, is now entertained by all philosophic anatomists; and it is necessary to keep it in view, when we speak of the arrangement of nerves proceeding from the shell. It is not in the highly developed cranium of Man that we must look for its verification; but in the lower forms of that structure, such as those presented by Fishes and Reptiles.

Although it may be stated as a general proposition that no *neuro-skeleton* exists in the Invertebrata, and that a jointed vertebral column is characteristic of the Vertebrated classes, some exceptions must be admitted, which occur on each side, and go to establish the connection between these divisions of the animal kingdom. Thus, in some Crustacea, we find the nervous cord, which runs along the ventral* aspect of the body, enclosed in a complete ring, formed by two projections from the external shell;

* In all the Articulata, the *ventral* aspect of the body corresponds with the dorsal surface in higher Animals. This is proved by the position of the umbilicus, and the general reversed position of the viscera.

these pass inwards, and meet on the median line. Even where the ring is not complete, these two projections frequently exist, and are evidently the rudiments of it. Again, in the Cephalopoda, a cartilaginous envelope surrounds the nervous centres; and this is but little inferior in organization to the simplest form which the neuro-skeleton presents in the Cyclostome Fishes. Thus, in the Myxine, there is no jointed vertebral column, but only a continuous tube of soft cartilage, exhibiting scarcely a trace of division into rings, on the outside of which the spinal cord runs. This tube contains a gelatinous substance, resembling that which is included in the intervertebral bodies in higher Fishes; so that it may be regarded in the light of a continuous intervertebral substance. In the Lamprey, there is a more distinct division into rings, but still the canal is continuous through all; and it is not until we advance much higher, that the division becomes complete between the solid bodies of the vertebrae, and the capsules of intervertebral substance which separate them.

When we look more particularly at the nervous centres themselves, we perceive that they combine the general characters of those of the Articulata with those of the Mollusca. In the former, the power of active locomotion seems the chief object to be attained; and the predominant part of the apparatus is evidently the series of ganglia connected with the locomotive organs. The sensory ganglia appear subservient to these, both in size and function. On the other hand, in the Mollusca the sensory ganglia predominate; and under their function, which is to direct these walking stomachs to their food, the control of the locomotive apparatus seems to be placed. Now, in the Vertebrata we have the locomotive powers of the Articulata (reduced, however, in activity), united with the complex nutritive system of the Mollusca; and we find this combination manifested, not only in the organs themselves, but in the nervous system which stands in so close a relation with them. The spinal cord of Vertebrata is evidently the analogue of the ventral columns of Articulata. It is a continuous ganglion, containing two portions as distinct as the two tracts in the Articulata;—a fibrous structure, which is continuous between the brain and the spinal nerves, and thus resembles the white tract in Insects;—and a ganglionic portion, principally composed of grey matter, or of a substance equivalent to it in character. In this grey matter, as in the ventral ganglia of Insects, a part of the roots of the spinal nerves are lost; whilst others may be traced to the brain. At the upper extremity of the spinal cord (commonly termed the *medulla oblongata*), we find the ganglia and nerves of special sensation; and the organs

which these supply are placed in immediate proximity with the entrance to the alimentary canal, and hold the same relation to it as in the Mollusca. But in addition to these, we find two ganglionic masses in all Vertebrata, to which we have no distinct analogue in the lower classes—the cerebral ganglia, and the cerebellum. With the development of the former of these, the perfection of the reasoning powers appears to hold a close relation; that of the latter seems connected with the necessity which exists for the adjustment and combination of the locomotive powers, when the variety of movements performed by the animal is great, and the harmony required among them is more perfect. Upon this latter point, however, much doubt still exists.

The visceral system of nerves now assumes a more distinct form. It does not share the protection of the spinal column; but its ganglia lie for the most part in the general cavity of the trunk. Microscopic examination of the structure of the visceral nerves and ganglia exhibits a considerable difference in their character from that of the cerebro-spinal system; as was stated in the first lecture.

The connections of the cerebro-spinal and sympathetic systems may be best studied in the trunk; since the regularity of the distribution of the spinal nerves prevents the existence of that doubt regarding the nature of the communication, which obscures the relations of the cranial nerves with the sympathetic. The visceral ganglia—namely, the cardiac and semilunar—may probably be regarded as the true centres of the nervous system of organic life; whilst the chain of ganglia, which lie along the spine, are intermediate between these and the cerebro-spinal system. When the filaments connecting these ganglia with the roots of the spinal nerves are closely examined, they are found to contain both kinds of fibres; and they can no more, therefore, be regarded as the *roots* by which the sympathetic system arises from the cerebro-spinal (as they were formerly described), than as the roots by which the latter originates from the former. The white tubular fibres which these filaments contain, are found, upon close examination, to be derived from both roots of the spinal nerves, and not from the posterior only, as some have supposed. The quantity of white fibres in the nerves proceeding from this lateral chain of ganglia is much greater than that contained in the nerves of the solar plexus; and it is confirmatory of the idea just stated—that the visceral ganglia are the true centres of the sympathetic system—to find that the nerves proceeding from them are almost entirely composed of the fibres characteristic of this system. A few grey fibres may be found in almost all the cerebro-

spinal nerves; they are particularly abundant, however, in the first division of the fifth pair. It would seem that only a part of these are derived immediately from the sympathetic nerve; and that the remainder may be traced into the grey matter of the ganglia formed on the posterior roots of the spinal nerves and on the larger root of the fifth pair. As this grey matter consists of nucleated globules, like those which are found in the centres of the sympathetic system, it may be surmised that this series of ganglia also may be regarded as belonging to the sympathetic system, and as having an influence on the grey fibres contained in the cerebro-spinal nerves, like that which the semilunar ganglia possesses over the nerves of the solar plexus. This is, at any rate, a much more probable account of the functions of these ganglia, than any which had been offered before their connection with the system of grey fibres was discovered by Remak. The notion once entertained that these intervertebral ganglia had some connection with sensation, because found on the posterior or sensory roots of the nerves, and that the ganglionic portion of the column of the Articulata must therefore be sensory, has, therefore, no adequate foundation. If anything be wanting to prove the want of real analogy between these parts, it is the fact that small ganglionic enlargements may be detected upon the nervous trunks proceeding from the ganglionic column of the larger Crustacea, at a short distance from their roots. These are evidently the analogues of the invertebral ganglia of the Vertebrata.

The branches proceeding from the semilunar ganglia are distributed upon the abdominal viscera; and those of the cardiac ganglion upon the heart and vessels proceeding from it. The latter seem to accompany the arterial trunks through their whole course, ramifying minutely upon their surface; and it can scarcely be doubted that they exercise an important influence over their functions. What the nature of that influence is, however, will be a subject for future inquiry. It is so evidently connected with the operations of nutrition, secretion, &c. that the designation of "nervous system of organic life," as applied to this system, does not seem objectionable, provided that we do not understand it as denoting the *dependence* of these functions upon it. Even in Vertebrata, however, we do not always find the visceral system distinct from the cerebro-spinal. In the Cyclostome Fishes, the par vagum supplies the intestinal canal along its whole length, as well as the heart; and no appearance of a distinct sympathetic can be discovered. In serpents, again, the lower part of the alimentary canal is supplied from the spinal cord, and the upper part by the par vagum; and though the lateral cords of the

sympathetic may be traced, they are almost destitute of ganglia. Even in the highest Vertebrata, some of the glands, of which the secretion is most directly influenced by the condition of the mind, are supplied with most of their nerves from the cerebro-spinal system; thus, the lachrymal and sublingual glands receive large branches from the fifth pair, and the mammary glands from the intercostal nerves. It may therefore be regarded as not improbable that the organic fibres contained in these nerves, and principally derived from the ganglia at their roots, are the most direct channels through which the processes of nutrition and secretion are influenced by mental emotions; and that the office of the distinct visceral system is rather to bring these functional changes into harmony with each other.

The spinal cord, with its encephalic continuation—the medulla oblongata, may be regarded as constituting the essential part of the nervous system of Vertebrata. Although the cerebral hemispheres in man bear so large a proportion to it in size, that the spinal cord seems but a mere appendage to them, the case is reversed when we look at the other extremity of the scale;—the cerebral hemispheres in fishes being but ganglionic protuberances from the medulla oblongata. Moreover, the fact that animals are capable of living without the brain, whilst they at once die if deprived of the spinal cord, sufficiently demonstrates this. The spinal cord, then, when viewed in relation to the nervous system of the Invertebrata, may be regarded as including their respiratory, stomato-gastric, and pedal ganglia. That these should be associated together can scarcely be considered remarkable. It is obviously convenient that they should all be enclosed in the bony sheath provided for their protection; and their closer relation favours that sympathy of action, which is so important in animals of such complex structure and mutually dependent functions, as the higher Vertebrata. An animal either congenitally or experimentally deprived of its cerebral hemispheres, is very much in the condition of one of the acephalous Mollusca. It can perform those respiratory movements on which the maintenance of its circulation, and consequently its whole organic life depend; it can swallow food brought within its reach, and it can, in some degree, exert its locomotive powers to obtain it; but it is unconscious of the direction in which these can be best employed, and is dependent upon the supplies of food that come within its grasp. The acephalous Mollusca are so organised that they find support from the particles brought in by their respiratory current; but the more highly organised Vertebrata are not capable of so existing, and they must have their food provided for them

by an exertion of the mental powers. So long as an acephalous vertebrate animal is duly supplied with its requisite food, so long may it continue to exist; and thus it is seen that the operations of the brain are rather connected with the *intelligence* than with the blind undesigning *instinct* of the animal.

It is only in the Vertebrata that the difference between the *afferent* and *efferent* fibres of the nerves has been satisfactorily determined. The merit of this discovery is almost entirely due to Sir C. Bell. He was led to it by a chain of reasoning of a highly philosophical character; and though his first experiments on the spinal nerves were not satisfactory, he virtually determined the respective functions of their two roots, by experiments and pathological observations upon the cranial nerves. Before any other physiologist came into the field. Subsequently his general views were confirmed by the very decided experiments of Müller; but until very recently some obscurity hung over a portion of the phenomena. It was from the first maintained by Magendie, and has been subsequently asserted by other physiologists, that the anterior and posterior roots of the nerves were both concerned in the reception of sensations and in the production of motions; for that, when the anterior roots were touched, the animal gave signs of pain, at the same time that convulsive movements were excited; and that, on touching the posterior roots, not only the sensibility of the animal seemed to be affected, but muscular motions were excited. These physiologists were not willing, therefore, to admit more than that the anterior roots were especially motor, and the posterior especially sensory. But the recently-attained knowledge of the reflex function of the spinal cord enables the latter portion of these phenomena to be easily explained. The motions excited by irritating the posterior root are entirely dependent upon its connection with the spinal cord, and the integrity of the anterior roots and of the trunks into which they enter: whilst they are not checked by the separation of the posterior roots from the peripheral portion of the trunk. It is evident, therefore, that excitation of the posterior roots does not act immediately upon the muscles through the trunk of the nerve, which they contribute to form; but that it excites a motor impulse in the spinal cord, which is propagated through the anterior roots to the periphery of the system. The converse phenomenon, the apparent sensibility of the anterior roots, has been still more recently explained by the experiments of Dr. Kronenberg, who has satisfactorily proved that it is dependent upon a branch of the posterior root passing into the anterior root at their point of inosculation, and then directing itself towards the centre; for it was found

by Dr. Kronenberg that the sensibility of the anterior roots was not diminished by the separation of them from the spinal cord, whilst it was entirely destroyed by division of the posterior roots; thus proving that the latter constituted the channel through which the impression was conveyed.

On the other hand, the distinctness of the system of nerves in the simply-reflected actions, from those which minister to sensation and volition by their connection with the brain, is by no means so obvious as in the invertebrated classes. When first pointed out by Dr. Marshall Hall, who had grounded his opinion more upon physiological phenomena than upon anatomical facts, the statement did not command general assent; since, while the phenomena were admitted, the inferences drawn from them by him were not regarded as necessary results. When, however, the anatomy of the nervous centres in Vertebrata was more closely inquired into, (by Mr. Grainger, who had been partly anticipated by Bellingeri), it was found to present certain phenomena which might be regarded as supporting Dr. M. Hall's views; and when the inquiry was extended to the Invertebrated classes, the confirmation was found to be still more decisive. In our previous sketch these doctrines have been treated as established; since they were found not only to correspond with the facts disclosed by anatomical research, but to be required by them. We shall now apply them to the nervous apparatus of the Vertebrata.

The spinal cord consists of two lateral halves; these are partially separated, in the higher classes, by the superficial anterior and posterior fissures; and in fishes by an internal canal, which is continuous with the fourth ventricle. This canal is evidently the indication of that complete separation of the two columns which exists in the lower Articulata; and the fourth ventricle, which, in many fishes, remains unclosed (the cerebellum not being sufficiently developed to overlap it), corresponds with the passage between the cords uniting the cephalic ganglia with the first suboesophageal, through which the œsophagus passed in all the Invertebrata. The two lateral halves have little connection with each other in fishes, and the pyramidal bodies at their apex scarcely decussate; but, in ascending towards the higher classes, the communication between the two sides is more intimate, and a larger proportion of the pyramidal fibres crosses to the opposite sides. In all the Vertebrata, the true spinal cord contains grey substance, or something equivalent to it; thus possessing the character of a continuous ganglion. The proportion of the vertebral column which this ganglionic portion occupies is, however, extremely variable; depending principally on the posi-

tion of the chief organs of locomotion. Thus, in the Eel, and other vermiform fishes, it is continued through the whole spinal canal; whilst in the *Lophius* and *Tetraodon*, whose body is less prolonged, and more dependent for its movements upon the anterior extremities, the true spinal cord scarcely passes out of the cranium. The quantity of grey matter is nearly uniform in every part of the cord, where there is no great diversity in the functions of the nerves which originate from each portion. In most fishes, for example, the body is propelled through the water more by the lateral action of the flattened trunk, whose surface is extended by the dorsal and caudal fins erected upon prolongations of its vertebrae, than by the movements of its extremities, which serve principally to guide it. Hence we usually find the amount of grey matter varying but little in various parts of the cord. But in the Flying-fish, and others whose pectoral fins are unusually powerful, a distinct ganglionic enlargement of the cord takes place where the nerves are given off. In Serpents, again, the spinal cord is nearly uniform throughout its entire length; whilst in Amphibia it is so during the tadpole condition (as in most fishes), but presents enlargements corresponding to the anterior and posterior extremities, when these are developed, at the same time becoming much shortened as the tail is less important to locomotion, or is altogether atrophied. In Birds, the ganglionic enlargements are generally very perceptible, and bear a close relation in size with the development of the locomotive organs with which they are connected. Thus, in birds of active flight, and short powerless legs, the anterior enlargement is the principal; but in those which are more adapted to run on land than to wing their way through the air, such as the whole tribe of struthious birds, the size of the posterior enlargement is very remarkable. Hence we have a right to infer that the increase in the quantity of grey matter in the cord has some connection with the amount of power to be supplied; and this exactly corresponds with what has been observed in the articulated classes, and especially in watching the metamorphosis of insects. In birds and mammalia, however, the whole amount of the grey matter in the spinal cord does not bear so large a proportion to the bulk of the nerves proceeding from it as in the lower Vertebrata; and the reason of this seems obvious. The actions of the locomotive organs are less and less of a reflex character, and are more directly excited by the will, and consequently by the brain, than in the inferior tribes; and just in proportion, therefore, to the development of the brain, will it become the centre of all the actions performed by the animal, and the spinal cord a mere appendage to it.

Still, in all the Mammalia, and in man, do we find these ganglionic enlargements of the spinal cord; and in man it is the posterior one which is most considerable. In the cord of this class, too, the lateral halves are much more intimately united than in the classes below; for not only is the central canal for the most part absent, but the two crescent-shaped plates of grey matter are united by a transverse lamella, which connects their centres like a commissure.

The cord is traversed not only by the anterior and posterior fissures, but by two furrows on each side, marking out three columns upon it. We have, therefore, on each half of the cord, an anterior, middle or lateral, and posterior column. The points of the crescentic lamellæ of grey matter approach these furrows pretty closely; but elsewhere the grey matter is covered deeply by the fibrous columns. We are speaking here of the spinal cord of the higher Vertebrata, the minute structure of which has been more closely examined than that of fishes. Each spinal nerve arises from two sets of roots. The anterior roots join the spinal cord near the anterior furrow; and the posterior near the posterior furrow. Regarding their intimate connection with the principal divisions of the cord, however, a considerable diversity exists among the statements of anatomists. In the first place, with regard to their connection with the fibrous and cineritious structures, it may be stated that a portion of the posterior set of roots unquestionably loses itself in the grey matter; whilst of another portion the fibres are continuous with those of the white columns of the spinal cord. There is more difficulty, however, in tracing the anterior roots into the grey substance. Still, however, the connection has been made out, although not in the human subject, by Bellingeri and Grainger; and there is reason to believe, therefore, that it is constant, although not readily perceptible. Of the portions of the roots which are continuous with the fibrous columns, it is stated by Sir C. Bell that the anterior fasciculi pass to the anterior columns only, and that the posterior are restricted to the lateral columns. On the other hand, Mr. Grainger and Mr. Swan maintain that both sets are connected with the lateral columns only; the anterior and posterior lateral fissures definitely limiting the two roots. Perhaps both these statements are rather too exclusive. The anterior roots would seem to have a connection with both the anterior and lateral columns; and the posterior cannot be said to be restricted to the lateral column, some of their fibres entering the posterior division of the cord.

As the white or fibrous portion of the spinal cord is continuous with that of the brain, it follows that the roots of the nerves which enter it are in reality thus brought

into connection with the cerebral hemispheres and cerebellum; and the posterior division of these may, therefore, be regarded as conducting to the brain the impressions which there become sensations; whilst the anterior roots convey the motive influence, which has been propagated, by a voluntary impulse, down the tract of the spinal cord with which they are continuous. On the other hand, the termination of one portion of each set of roots in the grey matter of the cord, completes the nervous circle required for the performance of reflex actions; and by this they would seem to take place in Vertebrate animals, just as through one of the ganglia in the Articulata. It follows, then, on this view of the character of the spinal cord, that the continuity of the fibrous tracts is all that is required to convey the influence of the will to the parts below; whilst the completeness of the nervous circle is all that is necessary for the performance of reflex actions excited through it. This is found to be strictly true; the former having been observed in cases of disease, and the latter having been proved by experiment. As far as simple reflex actions are concerned, there is as much segmental independence in Vertebrata as in the Articulata; but these actions seldom have so completely the character of adaptation, and are of a more irregular and convulsive nature. Still, however, there is an essential correspondence between them; and we may, therefore, regard the distinction between the reflex and voluntary movements as the same in each group; the former predominating in Articulata; the latter in Vertebrata. On this view, then, each spinal nerve contains at least four sets of fibres.

1. A sensory bundle passing upwards to the brain.

2. A motor set, conveying the influence of volition downwards from the brain.

3. Excitor or centripetal fibres, terminating in the true spinal cord or ganglion, and conveying impressions to it.

4. A motor or centrifugal set, arising from the same ganglionic centre, and conveying the motor impulse reflected from it to the muscles.

Of these the first and third are united in the posterior or *afferent* roots; the second and fourth in the anterior or *efferent* roots.

It is difficult to trace the course of the fibres within the spinal cord; and some recent experiments by Valentin appear to prove that Sir C. Bell was not correct in his idea that the functions of the columns of the cord are similar to those of the roots which are connected with them. Cases, indeed, are of no unfrequent occurrence, in which a portion of one of the columns has been almost entirely destroyed by injury or disease, without any corresponding loss of

the function attributed to it. Such cases have kept alive, in the minds of many eminent practical men, a considerable distrust of the accuracy of Sir C. Bell's conclusions. We have seen that, in regard to the roots of the nerves, his first statements have been confirmed, and rendered more precise, by subsequent researches; but it is not so in regard to the functions of the anterior and posterior divisions of the spinal cord. Bellingeri was led, by experiments on the spinal cord, to the conclusion, that the anterior roots of the nerves were for the flexion of the various articulations, and the posterior for their extension. He also was wrong, in extending an inference founded on experiments on the cord to the roots of the nerves. The recent experiments of Valentin, whilst they fully confirmed Sir C. Bell's determination of the functions of the roots of the nerves, coincide, to no small degree, with Bellingeri's opinion in regard to the offices of the anterior and posterior divisions of the cord. He obtained reason to believe that, in the frog, neither the superior nor inferior strands of the cord (posterior and anterior columns in man) solely possesses motor functions; but he found that, when the former were irritated, sensations predominated; and when the latter, motions were chiefly excited. He further states that, if the superior strand (*posterior column*) be irritated at the point at which the nerves of either extremity are given off, that extremity is *extended*; and that if the inferior strand (*anterior column*) be irritated, the extremity is *flexed*. At their entrance into the spinal cord, therefore, it would appear that the motor fibres of the extensors pass towards the superior stratum (*posterior column* in man), whilst those of the flexors are continuous with the inferior stratum (*anterior column*); their course being more altered, however, when they are examined far from the point of issue. This doctrine was confirmed by experiments on Mammalia; and is borne out (according to Valentin) by pathological phenomena observed in man. According to this eminent physiologist, also, relaxation of the sphincters is analogous to the extended state of the extremities; and he has noticed a manifest relaxation of the sphincter ani in the frog, when the superior part of the spinal cord was irritated, so as to produce extension of the limbs. These statements are entitled to considerable weight, on account of the quarter from which they come; but they are not, perhaps, to be received altogether without hesitation, until confirmed by other physiologists, especially whilst the phenomena of reflex action are still so imperfectly known. For it is quite possible that, whilst stimulation of the anterior part of the cord may directly excite the motions of flexion in preference to those of extension, the movements of extension

produced by stimulating the posterior column may be of a reflex character.

There is no reason to believe that the functions of the spinal cord are essentially different along its whole length. Every where it appears to consist of a ganglionic centre, supplying nerves to its particular segment; and of connecting fibres, by which the nerves proceeding from any one division are brought into relation with distant portions of the organ, and with the large ganglionic masses at its anterior extremity. In this respect, then, it corresponds precisely with the double nervous cord of the Articulata; the only prominent difference between the two being, that in the former the ganglionic matter is continuous from one extremity of the organ to the other, whilst in the latter it is interrupted at intervals; and in the Mollusca the centres are still further separated from each other. The connection of the spinal cord with the large ganglia contained within the cavity of the cranium is effected by means of processes from its superior extremity, the arrangement of which is somewhat complex. This portion of the cord, which also lies within the cavity of the cranium, has been termed the *medulla oblongata*. It has been supposed to be the peculiar seat of vitality; but the only real foundation of this idea is that it is the great centre of the respiratory actions, on the continuance of which all the other functions are dependent. The brain may be removed from above, and nearly the whole spinal cord from below, without an immediate check being put upon the nervous phenomena of life. In the *medulla oblongata* four different parts may be distinguished on each side: the anterior pyramids, or *corpora pyramidalia*; the olivary bodies, or *corpora olivaria*; the restiform bodies, or *corpora restiformia*; and the posterior pyramids, or *processus a cerebello ad medullam*. These we shall now trace downwards into the spinal cord, and upwards into the encephalon; and the description I shall employ is chiefly that recently given by Dr. John Reid, which appears to me the most satisfactory of the many which have been put forth.

The *anterior pyramids* decussate, as is well known, at their lower extremity; the principal part of the fibres on each side passing over to the other. The decussating fibres pass backwards and downwards, and enter, not the anterior column of the spinal cord, but the middle column, uniting with the fibres from the restiform bodies. The smaller bundle of fibres, which do not decussate, passes downwards along with those from the olivary bodies, to form the anterior column. A small band, however, proceeds backwards to join the cerebellar column: this is the arciform band of Mr. Solly; but was previously described by Rosenthal and Rolando.

The fibres descending from the olivary bodies converge, as those of the pyramids pass backwards from between them, until they meet on the median line, forming the greater part of the anterior column. The greater part of the restiform body descends into the middle column of the spinal cord, but the posterior part of it unites with the posterior pyramids to form the posterior column. Thus the *anterior* column of the spinal cord may be said to pass upwards into the olivary body, and the non-decussating portion of the anterior pyramid,—a small portion also communicating with the cerebellum; of the *middle* column, a part decussates, and passes forwards into the anterior pyramid, whilst another part ascends into the restiform body of the same side; and of the *posterior* column, a part ascends into the restiform body, and the remainder into the posterior pyramids, which do not decussate in man, but which are stated by Valentin to do so in the frog.

On tracing upwards the fibres of the *anterior pyramids*, they are found to enter the pons varolii, through which they pass, traversing the optic thalami, into the crus cerebri; they then diverge from each other, and become intermingled with grey matter, forming the corpora striata. The fibres of the *olivary body* also pass into the pons varolii, and there divide into two bands, of which one proceeds upwards and forwards to join the crus cerebri, whilst the other proceeds upwards and backwards to reach the corpora quadrigemina. Of the *restiform* body, also, a part of the fibres ascend into the crus cerebri, and pass on to the optic thalami, where they diverge and become intermingled with grey matter; whilst the remainder ascend, with those of the posterior pyramids, into the cerebellum.

Thus the anterior column principally terminates in the corpus striatum and corpora quadrigemina; the middle in the thalamus and corpus striatum; and the posterior in the cerebellum, which communicates, however, with the anterior also.

OBSERVATIONS

ON

THE TREATMENT OF ANEURISMS.

To the Editor of the Medical Gazette.

SIR,

SHOULD you deem the following remarks worthy of a place in your journal, you will oblige me by inserting them.—I am, sir,

Your obedient servant,

ROBERT DICKSON, M.D.

47, Finsbury Square,
March 19, 1841.

In the *MEDICAL GAZETTE* of the 26th of February, it is stated that, "On Saturday, the 20th instant, Mr. Partridge, at King's College Hospital, tied the subclavian artery in the first part of its course, for an aneurism which had existed in the vessel for about twelve months. After the operation pulsation was no longer perceptible in the tumor; and for the first two days the patient, who bore the operation very well, went on as favourably as could be expected. We believe that this is the sixth time that the operation has been performed, and in no case has the individual ultimately recovered*; for we regret to say that Mr. Partridge's patient died on the 24th."

The unfavourable issue of so many operations for aneurism alluded to in the concluding sentence, recalled to my mind some reflections I had indulged in on this subject many years ago.

In the year 1825, a patient in the Edinburgh Infirmary was operated upon by Mr. Allan for an aneurism of the femoral artery, by tying the external iliac. The patient died a few days after the operation, and, on inspection of the body, no inflammation of the neighbouring parts, or any other cause, deemed adequate to account for death, was found. It occurred to me that death was in all probability occasioned by suddenly throwing back upon the heart a large quantity of blood, not only disturbing its own action, but inducing a state of brain similar to what happens in certain cases of apoplexy. Determining to inquire further into this matter, I consulted the works of many writers on surgery, to ascertain if such a cause of death, and the means of obviating it, had been mentioned. I found no one had directly noticed it, but Richerand, in his "*Nosographie Chirurgicale*," had recorded a case (to be quoted in the sequel), which bore very closely upon it. I reflected, that if individuals who had submitted to amputation of any limb, in the course of the operation for which a considerable quantity of blood is lost, yet suffer from plethora, and the diseases consequent upon it, and apoplexy among others; and if even the slow suppres-

sion of many habitual discharges induced congestion of the vascular system, and oppression of the brain, how much more must this be the case with those who are the subjects of operation for aneurism, in which the blood which would have been diffused over perhaps a fourth part of the body, is confined to the other three-fourths.

In most of the operations for aneurism scarcely an ounce of blood is lost, as in Mr. Allan's case, where not a teaspoonful of blood flowed from the wound. This alone must disturb the rest of the system, not to mention the circumstance of a ligature being permanently around a large artery, which, like any other mechanical obstruction, always rouses the heart to increased efforts to overcome it, by which more blood is sent to the brain. A perusal of the fatal cases after operations for aneurism, which may be found in the pages of Cooper's *Surgical Dictionary*, will convince any one how many of the symptoms which preceded death are referable to this condition of the circulation. The great alteration in the heart's action, and, by consequence, in the state of the brain and nervous system generally, which immediately follows the application of a ligature around a large limb, or of pressure directly over a considerable artery, may be understood from the following facts:—

In Duncan's *Medical Commentaries* for the year 1795, vol. xix. p. 271, is a communication from Dr. Kellie, respecting an expeditious, simple, and effectual method of stopping the cold stage of an intermittent, and inducing the hot stage. It consisted in applying a tourniquet to the humeral artery in the right arm, and another to the femoral artery in the left leg. In the first case mentioned by Dr. Kellie, that of John Humphries, a second paroxysm of a tertian ague began at eleven o'clock in the morning. "When I saw him he was shaking very violently, and complained of headache and pain of the loins. Before screwing the tourniquets I counted his pulse; it was small and hard, beating just 100 times in 60 seconds. I now, as before, stopped the circulation in both extremities. I kept a watch with a stop and second before me, and found that, in three minutes from the obstruction of the circulation in the extremities, the cold stage entirely

* We believe that our reporter was not quite correct in this part of his statement. — *ED. GAZ.*

ceased, the headache was easier, and the pain of the loins entirely gone. I kept the tourniquets on ten minutes, and now counted the pulse, which I found soft and full, beating 120 in one minute. He was thirsty, but had no other complaint."

The same effects followed the application of the tourniquets in several other cases of intermittent; and Dr. Kellie resolved to try the effect of applying them to a healthy body; and from experiments on himself his report is—"I have thus determined their effects on the healthy body, and find that they occasion:—

1st. Great increase in the velocity of the circulation, as judged from the pulsation of the heart and arteries.

2d. Increase of heat and flushing of the face.

3d. Anxiety and more frequent respiration.

4th. The tourniquets being kept on more than six minutes, induce a tendency to syncope.

5th. The tourniquets being removed, and the circulation restored, the velocity of the circulation soon falls to its natural standard, and frequently considerably below it."

A part of Dr. Kellie's tabular view may be given:—

"Pulse 70, small, and rather hard, before the application of the tourniquet. After application, 90, full and bounding. The circulation being obstructed in two extremities for four minutes, heat and anxiety: I removed the tourniquets. 84, full and soft, the tourniquets having been removed."

In Mr. Wardrop's *Treatise on Diseases of the Heart*, published in 1837, appendix F, an account is given, by the late Mr. Hyslop, surgeon, of the recovery of a lady from severe syncope, after copious venesection, by the accidental compression of the brachial arteries in both arms, and a proposition by him, laid before the Royal Humane Society, to employ pressure by a tourniquet, or any substitute for one, to the humeral artery, for restoring the powers of life in persons apparently drowned, or in syncope. Mr. Hyslop was quite ignorant of Dr. Kellie's previous discovery, and his application of it was different; still the principle is the same, that of taking advantage of the obstruction by the mechanical compression of any consi-

derable artery, to increase the heart's action. In these cases the effect was beneficial: not so in aneurism, where, for the object of the operation, the ligature must remain, and the obstruction be permanent. Other means must be had recourse to, to obviate the evils resulting from this state of things. The simple expedient which I venture to propose is, to relieve the system of some of the superfluous blood by repeated venesections.

The history of a few cases of aneurism will, I trust, be sufficient to shew the soundness of this recommendation. I will begin with a successful case of operation, that of Mr. Liston's case of ligature of the subclavian artery, reported in the *Edinburgh Medical and Surgical Journal*, vol. xvi. p. 348, operated upon 3d April, 1820:—

"The patient for some time had been confined to the horizontal posture, bled repeatedly, purged, and religiously starved, according to the plan of Valsalva." Of the operation it is not necessary to say any thing, except that the external jugular vein was divided, and the lower end only secured by ligature, the upper being left untied; a circumstance to which, on attentive consideration of the case, it will, I think, be obvious that the man owed his safety. "The constitutional derangement consequent to the operation was slight. The pulse, in any part of the body, never was much above 100; nor did the action of the heart or large vessels seem at all disturbed. On the fourth day I dressed the wound, and found it adhering completely; but a little matter oozed along the ligature, with some small clots of blood. Next morning, betwixt twelve and one o'clock, I was sent for on account of violent hæmorrhage. On my arrival I found him a good deal exhausted, and surrounded with blood, apparently venous. On opening the wound the stream was perceived to issue from the upper orifice of the external jugular vein, which had given way on some slight exertion, after the clots had been removed by the suppuration. No other unfavourable occurrence took place."

So far from considering this hæmorrhage as an "untoward event," I conceive it was a most fortunate occurrence—a salutary dischargé, which relieved the brain and system generally from a superfluity of blood, which

would have produced mischief by its retention.

An unsuccessful case, by the same operator, seems to confirm this view. It is the case of John McIntyre, operated upon for subclavian aneurism; and recorded in the same journal, vol. xxvii. p. 4.

"Every thing went on well for some days. On the fifth evening after the operation, a good deal of excitement took place: the pulse, which had not risen above 90, beat 120, full and strong, and accompanied with an increase of pain in the tumor and arm. Eight ounces of blood were taken from the arm, and an anodyne afterwards exhibited, with great relief. Excepting the occasional exhibition of a laxative, no other remedies were had recourse to. On the morning of the thirteenth day, Dr. Sanders, who was so kind as to attend the patient during my indisposition, was sent for on account of slight oozing from the wound. In the evening a little more blood escaped, *with great relief of the pain and throbbing at the root of the neck, which had been all along very considerable, but which, for some days, had been remarked to be very violent.* The tumor also collapsed a good deal after the escape of the blood. Next morning (the 14th after the operation) a slight oozing of very dark and putrid blood again took place, and in the evening recurred to a considerable extent. It was arrested by compress, &c. but the patient did not again rally.

On reviewing the circumstances of the preceding case, I am perfectly satisfied that the fatal result is to be attributed to the unfavourable alteration in the coats of the arteries, and to the great size which, from its long duration, the tumor had attained."

I am far from denying that these may have had a share in producing the fatal result; but I think it clear that the excess of blood in the system was the main cause. We see vain efforts made to get rid of the superfluity, in each instance with relief, and I have marked with italics a passage indicative of the excited state of the heart and great arteries. Had venesection been practised then, and still more, on the first rising of the pulse, to the extent of thirty or forty ounces of blood, the result might have been different.

I will add a short notice of a case by

Mr. Syme, recorded in the same journal, vol. l. p. 372, of ligature of the common iliac artery. "In the course of the day (of operation) the tumor became smaller and softer. The coldness and discoloration extended above the knee, and the patient complained of inability to keep any thing on his stomach. On the 9th he was much in the same state. On the 12th he died. The peritoneum shewed traces of much inflammation, but not general or very extensive."

In this case the coldness and discoloration of the limb shewed how completely the circulation through it had been obstructed, and the inability of the stomach to retain any thing, shewed that the brain had already begun to suffer compression by the recoil of the blood from the obstructed artery. The limited inflammation of the peritoneum can scarcely be held to have caused death, though it may have aided in bringing about the event. But the case already alluded to by Professor Richerand is the most decisive, and the candour with which it is narrated is as instructive and worthy of imitation as the casualty to which it refers deserves to be avoided. "A man, strong and robust, entered the Hôpital St. Louis, for a popliteal aneurism. After preparing him by some laxative drinks, followed by a purgative, I operated upon him by Hunter's process, and during the operation the patient did not lose an ounce of blood. The patient, a man from forty to forty-five years of age, was muscular, and of full habit, the face red, and I should have caused him to be bled had I not counted on the operation that it would deprive him of a certain quantity of blood. I could have repaired that omission, by causing him to be bled after the operation. *I omitted this precaution, and my negligence, I confess it with pain, was, without doubt, the cause of his death.* In a word, every thing went on according to my wishes, till one evening of a hot and stormy day, for it was the month of July, and the thermometer (Reaumur) marked 24 degrees, the patient experienced a frightful apoplexy (*apoplexie foudroyante*): in a moment the face, the hairy scalp, the skin of the neck, became of a violet red colour; the eyes filled with tears; the mouth foaming; and in spite of six successive bleedings, the patient never recovered his intelligence, nor power of articulation. Next

day he was no more."—Nosographie Chirurgicale, p. 220, tome 4ieme, edit. 5ieme, Paris, 1821.

I submit these cases, and the practice recommended, with great deference, to the consideration of hospital and other surgeons, as they alone are competent to decide upon its propriety, or have the opportunity of carrying it into effect, should they approve.

TWO CASES

ILLUSTRATING THE EFFECTS OF CONTRE-COUP ON THE BRAIN.

To the Editor of the Medical Gazette.

SIR,

THE two following cases of injury of the head, which occurred within a short interval of each other, appear deserving of being placed on record, chiefly on account of what the *post-mortem* examinations disclosed. The appearances found on dissection in both cases, show how the same impulse, which, on the principle of *contre coup*, frequently causes fracture of the skull, in severe injuries of the head, to take place at the point opposite to where the blow was received, may produce a fatal bruising of the substance of the brain at the part opposite to the seat of the blow, even when the injury has not been so great as to cause fracture of the bone at the situation referred to; or, as one of the cases shows, when there has been no fracture of the skull at all. Some writers, in treating of *contre-coup*, and showing the application of that principle to "concussion" of the brain,* have adverted to the effects thus produced on distant parts of the brain by blows on the skull, independently of fracture: but I have not, in my reading, met with any cases that illustrate the results of this kind of injury in so striking a manner as those which I now beg to send you.

I am, sir,

Your obedient servant,
ALEXANDER SHAW.

Henrietta Street, Cavendish Square.

CASE I.—A. B. æt. 28. This man was admitted into the Middlesex Hospital, Feb. 8th, in a comatose state,

having two bruised and open wounds of the scalp, and it being reported that he had fallen, on the previous evening, from a considerable height. The wounds, which were near each other, were situated on the right side of the head, over the prominence of the parietal bone, and between that part and the sagittal suture. In one of the wounds the bone was denuded to an extent about the size of a sixpence. The patient could be easily roused from his stupor; and was then restless. He was frequently sick and vomited. His pupils dilated and contracted in obedience to the light. His breathing was tranquil.

For the first six days the treatment corresponded with what is usually adopted in cases of supposed concussion of the brain: he was first freely purged with calomel and jalap; was bled from the arm and afterwards cupped from the temples; had cold lotions applied to his head; and took calomel and antimony in small repeated doses, to the extent of making his gums sore. During this period he appeared to be progressively amending; he became more sensible, lying for a considerable part of the day awake, as if observing what occurred in the ward; answering questions at times to his friends or the nurse; and getting out of bed to void his urine or use the close-stool. The wounds of the scalp assumed an improved appearance and discharged healthy pus.

On the evening of the 14th, shortly after being so well as to answer a question put to him by the nurse, he was seized with a fit resembling an epileptic attack. For this he was bled from the arm by the house-surgeon; and a full dose of calomel and jalap was administered.

15th.—He has had several more fits. They consist of a spasm and convulsion confined to the right side of the body. Each fit commences by the head being drawn to the right side, the eyes being directed to the same side, and remaining fixed, as long as the fit lasts, in that position; the muscles of the right half of the body now become rigid, and presently the arm is alternately bent and extended, while the patient draws his breath in a succession of short rapid inspirations, accompanied with a crying sound. His stupor is increased; yet the breathing

* See a Clinical Lecture by Sir Charles Bell, MEDICAL GAZETTE, vol. xiii.

remains soft and tranquil, and both pupils obey the stimulus of light in an equal manner. The pulse varies in rapidity and force at different times.

16th.—There is not much alteration since yesterday. At first the fits were severe, but occurred only about once in every six hours; now they return frequently, and are of short duration. The calomel and jalap have been repeated, and a large blister has been applied to the nape of his neck.

Evening.—It is now observed that the right side of the body, besides being affected with the spasms above described, is paralysed. Yet he preserves sensation on that side. When pinched on the right side, he manifests distinct signs of pain; but it is by moving the left arm, not the arm that is pinched. His face being flushed, and the skin hot and dry, and the pulse hard, he was bled from the temporal artery to the extent of sixteen ounces.

17th, morning.—He is no better. A consultation having been called, it was resolved to remove with the trephine the portion of bone denuded in the upper part of the wound. This was done; but the dura mater underneath presented no unnatural appearance. The fits continued during the day as frequent and as severe as before. He was ordered a quarter of a grain of tartar emetic in water, every two hours.

18th.—There is no observable change in regard to the convulsions, except that they perhaps succeed each other more frequently than before, being sometimes three in the hour.

19th.—Early this morning he died.

Post-mortem examination.—Upon removing the skull-cap, the dura mater presented a natural appearance, except at the point corresponding with the trephined hole in the skull, where some granulations had risen. When the dura mater was reflected, so as to expose the brain, an effusion of blood was found extending over the lateral part of the left hemisphere: but upon the right hemisphere there was no similar effusion, or any morbid change. The effusion of blood on the left hemisphere formed a thin layer, spread equally over the surface, except at the temple, where the clot was more abundant. On examining this part (which, following an oblique line from above downwards, was to be accounted the point opposite to where the blow was re-

ceived) a considerable portion of the brain was found to be broken down to a soft pulp: and from this part it was obvious the blood effused around, and which extended likewise towards the base of the brain, had proceeded. The particular portions of the brain which had suffered this bruising of their texture to the greatest degree, were the anterior part of the middle lobe, which lies in the sulcus formed by the greater *ala* of the sphenoid bone; and the posterior edge of the anterior lobe, at the most external parts. No fracture could be perceived in any part of the skull.

CASE II.—A strongly built, muscular man, was admitted, at one o'clock P.M., March 21st, into the hospital, being in a state of insensibility, consequent, as it was reported, on a fall from a ladder. It was stated by his friends, that on the previous evening, while standing on a ladder about eleven feet from the ground, he fell backwards and lighted on his head. He immediately became insensible, and has remained in nearly the same condition till the present time. Last night he was visited by a surgeon, who bled him at the arm.

Upon examining the back of his head, a bruised wound of the scalp was found, situated over the tubercle of the occipital bone. The patient, although comatose, could be roused, when stirred and loudly spoken to, so as to open his eyes and put out his tongue. He slightly resisted, with both eyes, having the eyelids opened with the fingers. It was ascertained that the pupils were contracted. He was observed to move his arms and legs. His pulse was soft, and at 65: his breathing was noiseless and without labour. He was ordered a powder consisting of

Jalap, grs. xx., and Calomel, grs. v. To have his head shaved, and a cold lotion applied.

Upon being visited in the evening, his face was found flushed, with drops of perspiration on it; and the pulse was above 100, hard and full. He was ordered

V. S. ad \bar{x} vi.; and to commence taking Calomel, grs. ii., with Tartar Emetic, gr. $\frac{1}{2}$. every four hours.

22d, 3 o'clock A.M.—I was summoned to the hospital in the night, under an alarm that the patient was dying. It

appeared at the time that the attack had proceeded from mucus accumulated in the air-passages, and the patient had not strength to expectorate. He recovered after the house-surgeon had swept with his finger some thick mucus from the back of his throat. It was subsequently noticed that in his breathing, although it appeared easy, the thorax was remarkably fixed, so that its motion could scarcely be observed; and the attempts that he made to cough were feeble and imperfect. During this day his stupor appeared more profound. He allowed his arms to fall when raised, as if they were paralytic. His legs are never moved. His urine and fæces pass from him involuntarily. The pupils are still contracted. As his head was hot, and his pulse rather full, twelve leeches were ordered to be applied to his temples, and afterwards a bladder of ice to be kept to his head. The calomel and antimony are continued.

23d.—At five this morning he died.

Dissection.—Some ecchymosis was found at the back part of his head, where he fell. Upon removing the skull-cap, the dura mater presented its natural appearance. When this membrane was reflected, a layer of blood was found to be effused over the anterior parts of the right and the left hemispheres of the brain, being contained between the dura mater and arachnoid membrane. This blood was most abundant where the anterior lobes lodge on the orbital plates of the frontal bone. Here the brain was extensively bruised, and converted into a substance consisting of coagulated blood mixed with brain. The anterior lobes being sliced down, the injury was found, especially on the right side, to have reached very deeply; so that a communication existed between the broken-down part and the anterior cornu of the right lateral ventricle; and a considerable quantity of blood, obviously derived from the ruptured vessels of the bruised part, was extravasated into this ventricle, and extended likewise into the left ventricle. At the posterior part, where the blow had been received, no marks of injury to the substance of the brain could be perceived; on the contrary, both cerebrum and cerebellum presented a sound appearance at this part. Nevertheless, a fissure of the skull existed here. This fissure

began below the tubercle of the occipital bone, and was traced on the left side of the perpendicular ridge, to the foramen magnum. Although a careful examination was made, no injury of the skull could be detected in front, where the brain was so extensively destroyed.

FUNCTIONS OF THE IRIS.

To the Editor of the Medical Gazette.

SIR,

IF in the following view of the functions of the iris there is any thing new, and at the same time plausible enough to deserve consideration, you will perhaps have the goodness to submit it to the criticism of such of your readers as may take an interest in the inquiry.

The iris is subject to contraction from two different sources; the one vital, the other animal. The former kind of action is intended to mitigate excess of light, and thereby prevent injury to the retina; an arrangement which would seem indispensable, when we reflect upon the immense difference in the quantity of light impinging upon the eye at different times, from the first break of dawn to the full blaze of a meridian sun. For if the limits of sensibility in the optic nerve may be compared with that of the nervous system in general, it is evident that the retina could not react sensibly upon the lesser quantity of light, without suffering a destructive excitation by the greater. In modern terms this kind of contraction is said to be a result of the reflex function. The other action of the iris is voluntary, and intended not only to adapt the focal distance of the retina to the external distance of its object, but likewise to enable us to judge of that distance by the accompanying *sensation of effort*; the degree of convergence of the eyes and other inferences being auxiliary means to the same end.

It is generally admitted that a varying convexity of the cornea is the means by which correct impressions of objects at different distances are attained. But how it is effected is not satisfactorily explained. Some refer the phenomena to an inherent activity of the cornea, and others to the acti-

vity of the external muscles of the eye.

In the present state of physiology, perhaps no very cogent argument can be advanced, either to support or refute the former opinion; and it appears to the writer that the advocates of the latter are satisfied with a very clumsy mechanism for enlarging or contracting the segment of a sphere, so nicely adjusted as the necessity of the case here requires. On the contrary, a circular muscle attached to the circumference of the cornea, a bow-string apparatus in the interior of the eye, namely the iris, would seem just the kind of mechanism required. For it may be presumed to act equally upon every point of its attachment, and thus, by a kind of hour-glass contraction, elongate the diameter of the eye in the direction required; whilst in its laminated texture, resembling the springs of a coach, we find in the cornea a suitable provision for admitting alterations of convexity. Nor is this a singular instance, as every physiologist knows, of an organ presiding over a double function, the one vital, the other animal. It must, however, be observed, we cannot assign these two functions to the iris, without also recognizing two *points d'appui*—the external and the pupillar edges—and that neither of them is absolutely fixed. In graduating the light to the sensibility of the optic nerve, it is the outer edge that is chiefly fixed, whilst the pupillar edge is moveable, but in making a focal adjustment the interior edge becomes the *point d'appui*, and the outer one is moveable: for here, as in other sphincters which have a tendency to contract *suâ sponte*, we can by a voluntary effort either overcome or augment the contraction. The action of the musc. orbic. palpebr. may serve as an illustration. For in nictation, which may be compared to contraction of the iris through increase of light, (both being effects of the reflex function), the motion produced scarcely extends to the circumjacent parts, whilst a forcible closure of the eye-lids is attended by a depression of the eye-brows and a corrugation of the surrounding parts, evincing a centripetal action of the whole muscle. If the reflex action has a natural disposition to close the sphincters, we may surmise the reason, why, in foetal life, they are imperforate or

adhesive, and why also the pupil is closed in sleep; since it does not imply a relaxation of the muscle, but a predominance of the vital over the animal powers; of a constraint over a periodic energy. During our waking hours the pupil is kept dilated by the desire and wish to see, and the reflex action which modulates the light is in so far antagonistic to the voluntary; but there is another antagonism between the voluntary expansion and contraction of the iris when we accommodate our vision to the distance of the object. If this view be correct it will assist in explaining the phenomenon that, in transfixing our sight from a distant to a near object in the same line, as from a remote object in the landscape to a speck on the window, there is a sensible diminution of the pupil, which would not take place were the iris designed for no other purpose than the exclusion of light, since the eye in this experiment is exposed to the same volume of light in both cases. The motion observed in the iris of the parrot, and of birds in general, and which is described as voluntary, may perhaps admit of a similar explanation. The eyes are placed on each side of the head, so that they cannot both be brought to bear distinctly upon the same object. When no particular object is present to excite especially the animal's attention, both eyes are equally susceptible of impressions, but when the attention is arrested on either side, the power of vision is transferred principally to that side, and withdrawn in the same proportion from the other. It is well known that when we close one of our eyes the pupil of the other is proportionally dilated; the probable reason of which is, that it requires a stimulus twice as great from one organ as from two to effect the same nervous reaction. To the human species, however, it is not natural to see with one eye in preference to the other, nor can a simple effort of the will accomplish it. The enlarged pupil is therefore consequent and involuntary, whilst in the animals spoken of, which can only see attentively with one eye at a time, it may not seem irrational to conclude that it is a voluntary dilatation which confers the preference. Whether any analogy be traceable in the distended eyelids, as depicted in surprise, admiration,

horror, or any emotion implying a powerful effort of attention, I leave to the opinion of the reader.—I am, sir,

Your obedient servant,

ZETA.

MEDICAL GAZETTE.

Friday, April 2, 1841.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

ON MEDICAL COLLEGES.

WE return to Mr. Green's pamphlet on Medical Reform, the topics introduced into which were too numerous and important to be treated of in a single paper; and the portion we shall now choose for comment will probably come best at the present time, when the subject of improvements in one of our oldest and *model* universities has been so recently under consideration.

One of the positions on which Mr. Green most confidently rests is briefly this:—"That it is only in universities and colleges that we can expect to find the conditions under which an adequate medical education, and a suitable professional training, can be accomplished;" and he therefore trusts that we may yet see all the medical schools of the metropolis connected with colleges, in each of which we might find a school for elementary instruction, a senior department for instruction in those knowledges which are common to all the professions (the literary arts and sciences), and a medical department for the studies properly medical.

In an article recently published we shewed that a university education in the arts and sciences, bearing in any respect the characters, and insuring any reasonable portion of the advantages, of that pursued at (for example) Cambridge or Oxford, cannot be de-

manded of the majority of those who desire to be medical practitioners, for the irresistible reason, that they cannot afford it. But this objection applies only to the general instructional part of a university system. It has no reference to the disciplinal portion of it, nor to the mode of study adopted in colleges; and we cannot but admit that much benefit would accrue from the adoption of a certain degree of college-discipline and mode of tuition in medical schools.

Medical students commonly come to the London schools at the same age as others commence their graduation at a university; but under what different circumstances do the members of each class find themselves placed? We need not imagine, for every one must have known, instances in which two companions and fellow students have parted—the one to graduate at Oxford, or at Cambridge; the other to walk some hospital. The first is consigned to the charge of a tutor who is responsible for his intellectual and moral culture; his whole course of conduct and management is laid down for him; he is made amenable to well-planned laws of discipline; he is entered a member of a society whose rules he is compelled to obey, to belong to which is deemed an honour, and to disgrace which is punished with the hundred-fold disgrace of the delinquent; every inducement to diligence and propriety that ambition, interest, self-respect, and social order can suggest, is held out to him; as far as possible his domestic comfort is provided for; and he is placed in a position, of all that can be imagined the most enviable for one with his objects. Of all men under discipline the graduate is the least sensibly, though in reality very strictly, restrained; and of all possible circumstances, those in which he is placed have always appeared to

us the most nearly to perfection adapted for the cultivation of the intellectual and moral character. That in many cases even these circumstances fail to produce their intended effect, is only a proof that they partake of the imperfection common to all things; but, on the other hand, the brilliant results that they have fostered, and which are evidenced in the matchless learning and eminent morality which, issuing from our universities, have spread their influence over all the land, and have so much contributed to place England highest in the scale of civilized nations—these are fully sufficient to prove that the system could not be generally imitated without producing the most desirable consequences.

Now, let us contrast with the circumstances of the university graduate, those of the medical student, who, up to this period of his life, has been placed under the same or very similar circumstances. On his arrival in London he is left, in ordinary cases, entirely to his own guidance; often, the choice even of the school at which he shall study is left to his own discretion; and in the best of cases he is only furnished with letters of introduction to one or more of his future teachers or hospital surgeons, from whom all that he can expect to receive is a certain amount of advice as to what courses of lectures he must enter to, and what general scheme of instruction he must follow. Beyond this he receives no counsel and is entirely unguided; his choice of residence, of associates, and of mode of life, are left entirely to himself; and he is thus abruptly, and unguardedly, placed in circumstances, of which, for one that will lead him to steadiness and application, a hundred will tempt him to idleness, and to the waste of the brief time that is allowed him for acquiring the knowledge that must serve him for his life. The circumstances of the

young medical student in London are in a word, almost as utterly hostile to his progress in professional knowledge, as those of the university graduate are favourable to the culture of the intellect; and it is a matter of surprise to us, not that so many, but that so few of the former, lose all the advantages that they ought to obtain from their attendance at the schools.

Of course all these things can only be said *in general*. In numerous instances, talent, and the love of exercising it, ambition, necessity, a naturally steady disposition—one or all of these, are sufficient to resist the pressure of circumstances, and the medical student, in spite of all the disadvantages of his position, works on, and attains an admirable result of professional knowledge. But if he does this, it is in spite of his circumstances; whereas, if a university graduate of the same disposition and talent does not obtain a similar result, it is in spite of his circumstances that he fails; on himself alone can the blame rest.

If these things be only generally true, it must be evident that advantage would result from the introduction of a certain amount of College system into our medical schools. The mode in which this might be effected it is certainly difficult to suggest; yet we do not think the obstacles to it are insuperable; and indeed, as far as the projection of a scheme goes, we believe they have already been surmounted at Guy's Hospital. It has, we understand, been long in contemplation there to have rooms provided in the precincts of the Hospital for all the medical students, with a common Hall and *Commons*, and to appoint tutors, who should both guide the studies, and exercise a certain control over the conduct, of their students; to form, in short, as far as possible, a medical college on the plan of the Colleges of our

Universities. But we fear that it is in Guy's Hospital alone that the main difficulty, resulting from the opposition of the Hospital Governors, is already, by the energy and good sense of the Treasurer, overcome; in others, a scheme of the same kind would probably, for a time, be thought inadmissible. However, there can be little doubt, if the advantages which a scheme of this kind would offer to the students were fairly set forth, this opposition from the Governors of hospitals would not long continue. The same common-sense which induced their predecessors slowly to open their wards for clinical study, and then slowly to permit the erection of theatres, dissecting-rooms, and laboratories in the hospital precincts, and which has now, at length, induced the hospital authorities, in nearly every instance, to afford to the interests of the medical schools much of their encouragement, and sometimes even a portion of their funds, would doubtless be sufficient, in time, to lead them to admit the propriety of having a regular establishment for those whom they now recognize as scarcely more than permitted visitors.

Supposing this difficulty (which, moreover, would exist only in those schools that are attached to the large hospitals) to be overcome, the following may be mentioned as the main objects to be had in view in the conversion of what are now mere day-schools into colleges. A home should be provided for as many as possible of the students, by providing furnished rooms for them in one or more buildings in the immediate vicinity of the hospital and school; these buildings being kept exclusively for the students and their tutors, of whom one or more should be resident. The first year's students, especially, should be thus provided with rooms, and if the number of

students were greater than could be accommodated, the seniors among them should be those obliged to reside without the College walls. There should be a common hall for dinner, for which each student should pay a certain moderate sum during his residence; breakfast commons should be provided at some reasonable rate, for all residing in the College; and servants should be appointed and paid by the College authorities, to attend each on a certain number of the resident students. In all these and similar things of domestic management, the system now prevalent in Cambridge, or Oxford, (and which, as it is the result of some centuries of experience, is probably more nearly perfect than any new one that can be suggested), might be followed; and we are quite sure that if a College system were adopted, even no further than this, it would be sufficient to change the mode of life of the medical student, which is now most dangerous or most uncomfortable, for one which would afford a high degree of social comfort and security.

But the system should not rest here. It should be the duty of the tutors to have the superintendence not only of the domestic arrangement of the Colleges, but of the studies of the pupils. From no small experience we are convinced that one of the greatest difficulties the student has to contend with is his ignorance of how and what he is to study—a difficulty so great, that the majority even of those best disposed to work utterly lose their first three or four months in trying to find out what they should study, or in a vain attempt to study every thing, or in learning that which they had far better postpone to a later period. And even when one does hit upon the right object of pursuit, it is no easy matter for him, if his mind have not been more than commonly disci-

plined, to determine how he should study, or to decide from time to time how much he knows, and, judging from his past progress, to tell what his further course should be. At present, the only guidance a student can find in these difficulties is the advice of one or more of his teachers; but to any one who is cognizant of medical schools we need not say that this is quite insufficient. Besides, the difficulty is commonly one which, though important, is not felt till it is too late; till, at some examination, the student finds himself deficient in a subject at which he had perhaps worked hard, and with which he had thought himself familiar.

To remedy all this, the only sufficient plan that we can imagine is one that would realize a more personal and individual instruction; one in which each student separately should be under guidance, and in which the mind of each should have that direction given to it for which it is best adapted, or which is most necessary. Nor do we know any system by which this can be carried on except that of tutors, who, not being lecturers, or in addition to their lectureships, should be constantly examining every student of the school, and appointing to each his appropriate work.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

March 23, 1841.

DR. WILLIAMS in the Chair.

Observations on the Blood Discs and their contents. By JOHN QUEKETT, Student of Human and Comparative Anatomy at the Royal College of Surgeons. [Communicated by Dr. Pereira.]

THE author's observations in the paper whose title has just been given, lead him to the following conclusions:—That each red particle of human blood is a flattened circular disc, consisting of an outer membrane or envelope, with a gelatiniform fluid in its

interior, which, under certain circumstances, is capable of becoming granular, and of escaping from the envelope in the form of small globules, the general number from each disc being about six or seven; and that the discs may present either a bi-convex or bi-concave surface: the latter form being by far the most common.

The author has hitherto failed in making out the existence of a central spot or nucleus, as usually described. He declines stating for the present what he has ascertained the contained globules to be, intending to lay before the society, at some future period, not only this but also an account of the important part played by them in some of the effects of inflammation.

The author describes at considerable length the appearances presented by the granules, both in the act of escaping from the discs and afterwards, pointing out the confirmation furnished by his observations of the correctness of the description given by Leuwenhoeck of the appearance presented by the globules of blood; that distinguished observer having described each disc as composed of six smaller ones. The author's description was illustrated by a series of drawings of the discs and granules, as seen in the microscope.

A case of partial Softening of the right Corpus Striatum and left Lobe of the Cerebellum, with imperfect Paralysis of the left Arm and right Leg. By Dr. BARKER.

THE patient is described as having suddenly lost all sensation, and almost all power of motion, in the left arm and right leg; neither the intellect, nor any of the organs of sense, having been affected before, or being affected after the attack. The only preceding symptom had been muscular weakness.

She appeared to have undergone a fit, which lasted half an hour, about five months before.

Between her admission into St. Thomas's Hospital, Sept. 15, 1840, and her death, she regained the complete power of retaining her evacuations, which had been lessened, though not destroyed by the last attack; and up to the 3d of November her other paralytic symptoms had diminished. On that day a fit occurred, and was repeated on January the 6th, 13th, and 23d. In a few hours after the last fit she died.

Her pulse had been uniformly slow and feeble. Her strength had been supported, and no active treatment adopted.

Serum was found on examination under the arachnoid of the brain; otherwise it was healthy, except in two points, in which there was a softened portion of a medullary substance, namely, in the right corpus striatum, and the left lobe of the cerebellum.

The cause of death in this case the author presumes to have existed in the softened points, which he considers as not of the nature of apoplectic clots, or of ramollissement, and he considers the mode in which this lesion produced death as different in kind from what is usually observed where organic disease after long quiescence becomes the cause of death. He presumes, therefore, that this event was attributable to disease distant from the part primarily affected.

The author in conclusion points out the discrepancies between the phenomena of this case and the general rules laid down in regard to the relation between affected portions of brain and the paralysed parts of the body, and expresses his opinion that these rules at present rest on an imperfect foundation.

No discussion took place of sufficient interest to report.

[The next meeting of the society will be on Tuesday, the 13th instant.]

MR. BATTLE'S LABORATORY.

To Sir Henry Hallford, Bart.

SIR,

IN addressing you on the subject of Pharmaceutical Medicine, I must, in the first instance, beg to be allowed to thank you for the numerous opportunities you have afforded me at the College of Physicians of submitting to the profession this class of medicines, and for the permission you have been kind enough to grant me at this season again to cover the College tables with the best samples which the market and the laboratory can furnish.

The object of my addressing you at the present time is to announce the approach of the season for preparing the narcotics. To this class of medicines I have for many years paid especial attention; and I am now convinced that their efficacy depends, in a very great degree, on the mode of their preparation. To improve this, as far as possible, to ascertain the principles and compounds which are essential to the production of their several effects, to retain the useful and reject the useless, has been my aim; and I believe that the constituents of these medicines are *still* imperfectly understood. Feeling most anxious for the improvement of pharmaceutical medicine, I trust I may, with your sanction, submit to the profession the experience I have gained. I purpose at a future time to communicate through the press such part of it as can be committed to writing; but nothing short of *actual inspection* can convey a clear and satisfactory idea of the process which is adopted. I beg permission, therefore, to ask the attendance of any members of the College and of the

profession generally, who may feel disposed to favour me with a visit at my laboratory, to witness the dissection and preparations of the principal remedial agents. The first, in order of time, will be Conium, on which, should the weather continue favourable, I shall commence operations on Wednesday, the 7th of April. The next article will be Hyoscyamus, and the next Belladonna. The remaining recent plants, as Aconite, Digitalis, &c. will be operated on as they come into season; and the other articles of the *Materia Medica*, as Aloes, Cinchona, Opium, &c. in alphabetical order. All my previous operations on these and other drugs are recorded at length in the *Laboratory Journal*, which is at all times open for inspection.

I am, sir,

Your obedient servant,

RICHARD BATTLE.

Laboratory, Cripplegate,
March 29, 1841.

MEDICAL REFORM.

To the Editor of the Medical Gazette.

SIR,

DURING the present time the question of medical reform has excited the attention of the profession from one end of the kingdom to the other; and however secluded the place may be, and however antiquated the notions and customs of the town or neighbourhood in which a member of the profession may pursue his calling, yet in some way or other the cry of reform reaches him. This has been the case with myself; and I have been led to reflect somewhat on the various measures proposed.

The grand principle advocated, if I may judge from certain articles in recent numbers of a contemporary journal, appears to be the amalgamation of all classes and orders of the profession! Now, taking this proposition for granted, let us just consider how far it would be conformable with justice towards a large portion of the profession, as at present constituted; and also how far the public would benefit by such a change.

And first, how far would it be just? Let me be allowed to put forward my own case by way of example. After spending sixteen years at home and abroad (during which period I enjoyed advantages not attainable by all) in the acquirement of medical knowledge, and having, during that time, passed the examinations at Apothecaries' Hall, and the College of Surgeons in London, as also a medical board abroad, and obtained the degree of Doctor in Medicine after three years' residence at the University of Edinburgh, and my license from the College of Physicians in London, I sat myself down to endeavour to reap some remuneration for the large sums expended, and time occupied,

in the acquisition of a knowledge of my profession. The rest of my professional brethren, holding the same rank as myself, have, in general, been similarly circumstanced: a certain proportion, it is true, have perhaps devoted more time to literary attainments; but all have been obliged, by existing regulations, to devote a large proportion of their time to the acquisition of medical knowledge.

Let us now take another case. A young man is apprenticed to an apothecary or surgeon for a period of five years; at the expiration of that term he goes to London, and in less than three years he may obtain his certificate from Apothecaries' Hall, and diploma from the College of Surgeons. Now if he has "worked hard," and has talent, he will usually be found a tolerably well-informed young man, and a few years in subordinate practice will fit him to be a most useful and intelligent general practitioner; but can he have the knowledge of medicine, and its collateral branches, possessed by the person who has devoted perhaps one-third of the period of his existence in its attainment? Again, if instead of having been an attentive and hard-working student, he has employed a "grinder," in order to gain a sufficiency of information to enable him to pass his examinations, what, let me ask, is the amount of knowledge possessed at the end of a year or two by this aspirant to public confidence? He may have got through his examinations with seeming credit, especially if he be possessed of iron nerve and ready impudence; yet ought such an one (and there are many such) to be placed on an equality with the studious and well-educated physician? The same confidence and impudence which have enabled him to pass his examinations will prove his friend throughout his professional career, and he will indeed be the "licensed quack." It is true he may meet with rebuffs, and experience difficulties, which would bow down the spirit of the conscientious man, but the mind of the impudent quack is too callous to be affected by any rebuke either of conscience or his fellow practitioners; and yet, should the amalgamation system be adopted, this individual would be admitted to the same rank and privileges as those enjoyed by men who have passed their best years, and perhaps expended a small patrimony, in attaining rank and honourable distinction in their profession! Now, would this be just? The public generally cannot understand all the intricacies of the subject; they are led to imagine a person who practises as a physician is one who has a certain claim to their confidence from superior information and experience, and they are willing to reward him accordingly; nor ought they to be deceived. It will, perhaps, be answered that there is

to be a certain standard of information demanded and ascertained by rigid examination for all classes of practitioners: and this will lead me, secondly, to consider what benefit will accrue to the public by the proposed change. What, let me ask, are the great mass of persons constituting the medical profession? They belong usually to the better sort of the middling classes, whose means are too limited in general to allow of the time expended, and expense necessarily incurred, in order to pass such an examination as that implied as the standard. I am willing to allow that we should still have a large body of well-educated physicians; but where would be the useful and intelligent general practitioner? If no grades are to be observed, or no distinction held forth as a stimulus, who will toil for years, and expend his substance, to become—what? a general country practitioner! And by the way, do not for an instant imagine I intend to cast a reflection on that most useful, intelligent, and ill-requited class: far from it, I respect and honour them, and believe them, though inobtrusive, to be, as to their merits, one of the most efficient and useful bodies in this or any other country. But their duties are arduous, and they are generally ill paid, and, as I have before remarked, but few, if any, would be willing to expend the capital and time required, in order to take upon themselves, under the amalgamating system, the toil and responsibility of the country practitioner. Too many fields for enterprise are open to countenance an opposite belief, and I need only revert to the comparatively few parents who are now willing to place their children in our noble profession. Who are to take the place of the apothecaries under the proposed system? Perchance the present race of chemists and druggists. To use a quaint saying, "If all are to be captains who are to pull in the boat?" Who would there be to minister to the wants of the extensive class of the better order of poor? If we make the standard of knowledge too high, a great proportion of highly useful members must be lost to the profession, and the public must be the sufferers; on the other hand, if too low, we degrade and injure instead of exalting the profession. Merit combined with talent, like oil, sooner or later, always rises to the surface, and exacts that deference from society which superior intelligence always commands. The general practitioner has always the opportunity of becoming a physician, should his claims to the distinction be founded in truth and a just estimate of his own attainments. This is a country in which no bounds are set to a man's rise: the highest offices in the realm are alike open to the mean and poor as to the proud and rich, should the genius and intellect command so exalted a station.

A summary of the foregoing would lead us to the conclusion that the standard of education, under the system proposed, would be too high for all classes, in consequence of which the important labours of a large body of highly useful persons would be lost to society; or, that it would be placed so near mediocrity that those endowed with higher powers and intellectual attainments would seek distinction elsewhere. In any way a system of amalgamation must prove injurious both to the public and to the best interests of the medical profession: as well place upon an equality the barrister and the country attorney:—the idea is preposterous! If a man has no talent he will never rise. The man who is placed by the public choice in an elevated station above his fellows may be deficient in some points, but be sure to excel in others; and perhaps, though his acquirements are not brilliant, they may be solid, and highly useful to his fellow men. How many are there whose knowledge of medicine in its various branches is of the highest order, and yet who have not the faculty of applying that knowledge. Certain reforms would undoubtedly be beneficial both to the profession and the public; but let them proceed from a legitimate source, and not from the outcry of a few interested individuals, who seek only their own aggrandisement, careless of the honour of the noble profession to which they unfortunately belong, and heedless of the ultimate consequences to society at large.—I am, sir,

Your obedient servant,

A PROVINCIAL PHYSICIAN.

March 26, 1841.

THE COMPOUND CATHETER.

To the Editor of the Medical Gazette.

SIR,

It may terminate the discussion between Dr. Andrew Buchanan and Mr. Foulkes, on the subject of the priority of the invention of the compound catheter, which has been carried on in some late numbers of the *GAZETTE*, to inform them that it belongs to neither. In M. Gerdy's treatise "*Des Bandages*," at page 123, vol. i., the following extract may be found. He is describing a tube to conduct the small instrument to the obstructed part of the urethra, "which tube," he says, "may be filled up by other tubes of smaller diameter," and adds, "*Les canules de remplissage doivent être d'inégal volume, entrer à frottement l'une dans l'autre et dans le conducteur, de manière que l'on puisse y en introduire une ou plusieurs pour remplir et retrecir à volonté son canal.*"

This proceeding of Gerdy's is referred to in Dr. James Arnott's late work on Strictures

as an improvement or alteration of a plan which he had himself recommended, and which has been introduced to the professional public by Ducamp as his own invention. This consists in passing a wide canula as far as the stricture, through which a smaller instrument may be passed, or a number of small bougies may be passed at once, and the endeavour made to carry one after the other through the stricture.

All these plans are essentially the same, and no doubt each may have its advantages under peculiar circumstances. A thick elastic gum canula (or consisting of other flexible material), having a bore only large enough to allow a small catheter to pass, differs in some respects from all the varieties that have been proposed, and would probably, from simplicity and economy, be superior under ordinary circumstances to any of them. It would, from the bluntness of its point, pass down the urethra with ease; from its easy flexibility it would accommodate itself to the natural curve of the canal, and thus convey the instrument intended to penetrate the obstruction to its centre.

I am, sir,

Your obedient servant.

CHIRURGES.

ON THE ACTION OF CERTAIN INORGANIC COMPOUNDS

WHEN INTRODUCED DIRECTLY INTO THE
BLOOD.

By JAMES BLAKE, Esq., M.R.C.S.

THE following is a short abstract of a memoir lately read before the Royal Society:—

The present paper is a continuation of a memoir read at the Académie des Sciences of Paris in 1839, and entitled, "*Effets de diverses substances salines, injectées dans le système circulatoire.*" (See *Archives Générales de Médecine*, Nov. 1839.) After some preliminary remarks, the author gives a list of the various substances of which he noted the effects, when they were severally injected into the venous or arterial systems, arranged according to the nature of these effects. The substances experimented on were the salts of magnesia, zinc, lime, strontia, baryta, lead, silver, soda, potass, and ammonia. The author carefully inquires into the phenomena, apparently arising from the direct contact of each of these substances with the animal tissues, and more particularly into the effects produced on the heart, on the muscular and nervous tissues, and on the pulmonary and systemic capillaries. The general conclusion which the author is led to draw from these researches is, that there exists a close relation between the chemical properties of the

substances experimented upon and their physiological effects; his experiments tending to prove that, when introduced into the blood, substances that are isomorphous exert similar actions on the living tissues. He notices, however, two exceptions to this law; namely, the similarity of the actions exerted on the pulmonary tissue by the salts of lead and silver, although these salts are not isomorphous; and also the action on the nervous tissue of the salts of ammonia being different from that of the salts of potass. But he remarks that the oxide of lead bears a close analogy to the oxide of silver in its relation to organic compounds; and also that the salts of ammonia, in separating themselves from those of potass by their action on the nervous tissue, yet become closely connected in this respect with the poisons derived from organic substances, with which their chemical composition is so strikingly analogous. The general fact, previously announced by the author, in his memoir read to the Academy of Sciences, at Paris, namely, that salts with the same base have analogous actions when introduced directly into the blood, may be considered a corollary of the above law.—(*Athenæum*.)

HISTORY OF THE LAST
ILLNESS OF SIR A. P. COOPER, BART.
AND
EXAMINATION OF THE BODY AFTER DEATH.
(From *Guy's Hospital Reports*.)

FOR many months previous to his last illness, Sir Astley Cooper had occasionally experienced great dyspnoea, upon the slightest exertion: and it had been observed by his friends that the peculiarity of his complexion bespoke some serious impediment to the circulation. It was not, however, till about six weeks before his death that he found difficulty in assuming the recumbent posture; and about that time he began to pass the greater part of his nights in the arm-chair, rather than attempt to lie down. He still continued to see a few patients during the day, both at home and at their own houses. He now became the subject of frequent cough; which was immediately brought on, if he attempted to recline. The gout, of which he had for several years experienced periodical attacks, showed itself imperfectly in the fore-finger of the left hand; and his legs began to swell, owing to the depending position in which they constantly remained.

During all this time he refused medical aid; and it was not till the 22d of January that he consented to see any one, to whom he might state his symptoms. At the time he was first visited, he was sitting in his chair, with his body inclined forward, and

his chin nearly resting on his chest; the pulse accelerated; not the slightest *bruit* nor abnormal sound in the heart, though the beat was extensive, and heard quite to the right side of the chest. The lungs afforded considerable bronchial rattle, but were neither consolidated nor compressed, and filled both cavities of the chest.

Although remedies appeared more than once to produce a temporary remission of his symptoms, and a further attack of gout in one foot seemed to afford some relief to the chest, yet, upon the whole, the disease advanced, and was attended by frightful fits of dyspnoea, during which his face was purple and his mind confused; and it was in one of these paroxysms that he died, on the morning of the 12th of February.

Shortly before his death, Sir Astley Cooper expressed a wish that the appearances which should be presented on the inspection of his body might be recorded in the *Guy's Hospital Reports*. He had particularly alluded to four points, the investigation of which he thought desirable;—a cured oblique inguinal hernia; a cured umbilical hernia; some suspected indications of phthisis in his youth; and an inability to sleep whilst lying on his left side.

Examination of the body of Sir Astley P. Cooper, Bart., in the 73d year of his age, on February 13th, 1841, at 9 o'clock in the evening, 32 hours after death, by Mr. John Hilton, in the presence of Dr. Chambers, Dr. Bright, Mr. C. A. Key, and Mr. Edward Cock.

The weather was warm and damp: there were slight cadaverous indications, from gravitation towards the posterior part of the corpse: the face and anterior surface of the body exsanguine: there was general and extensive oedema of the lower extremities; but no evidence of serous infiltration in the arms, nor in any other part of the surface of the body.

The head was not examined.

A globular projection, about the size of a large nut, was found at the umbilicus; which receded on pressure, leaving a well-defined rounded aperture in the linea alba, capable of admitting the end of the little finger. This protrusion consisted of a few congregated lobes of fat placed immediately behind the umbilicus, between it and the peritoneum, the free surface of which was corrugated, and presented a puckered appearance, most probably inflammatory, and the result of the artificial curative means which had been employed for a long period during life.*

* Sir Astley Cooper wore a piece of cork adapted to the umbilicus; and maintained in its place by straps of adhesive plaster, during many years, and until his fatal illness.

The anterior, thoracic, and abdominal parietes were covered with a layer of fat, about an inch in thickness, soft, and oleaginous. The muscular tissue exposed during the inspection was pale, soft, and flabby: indeed, the latter expression is applicable to nearly all the tissues. No gaseous or fluid effusion was found in the cavity of the peritoneum: the greater omentum, loaded with adipose matter, was contracted, and did not extend downwards more than two inches from the transverse colon. Some very old membranous adhesions existed between the right angle of the colon and the gall-bladder: cadaveric transudation of the bile from this viscus had slightly tinged the surrounding parts.

The viscera occupied their natural positions; excepting the cœcum, which was completely invested by the peritoneum, and hence less fixed than usual.

The liver healthy in form: some parts of its surface were slightly contracted and uneven; and sections of it presented hepatic venous congestion, approaching what is termed a "nutmeg appearance."

The gall-bladder was small; and contained a moderate quantity of healthy bile, which, upon gentle pressure, passed rapidly into the duodenum.

The spleen was rather larger than natural, its capsule a little opaque, and the interior of the organ very firm; a section presenting a smooth solid surface of a purplish grey colour.

The stomach was large, and distended with gas; the cardiac extremity stained brown by cadaveric transudation, or the action of the gastric fluid upon the blood: its tissues appeared quite healthy.

The small intestines presented nothing abnormal: nor was there any thing remarkable in the large intestines, excepting the dilated condition of the cœcum, the parietes of which were thin; its mucous membrane congested.

The pancreas was healthy.

The kidneys were surrounded by a considerable quantity of adipose tissue, remarkably dense, and very firmly adherent to the fibrous capsule of the gland. Both kidneys were much congested with blood, rather larger than natural, their surfaces mottled, and slightly granular. These morbid conditions were most evident at the lower part of the left kidney; less advanced but more generally diffused, in the right: and on the anterior surface of the latter, near its convex edge, were found two small cysts, containing a straw-coloured fluid.

The supra-renal capsules were healthy.

The urinary bladder was healthy and contracted, and contained about two drachms of whitish turbid urine.

The internal abdominal ring, on the left

side, was rendered distinct by a tubular extension of the peritoneum for about an inch into the inguinal canal.

A depression existed in a corresponding situation on the right side, the bottom of which was firm, irregular, and corrugated; and upon very careful examination, a minute serous canal, not more than a line in breadth when opened, was traced extending from it, along the spermatic cord, into the cavity of the tunica vaginalis, being the remains of a congenital inguinal hernia.*

Upon raising the sternum and cartilages of the ribs, both lungs were brought into view; and retained their expanded condition, overlapping the pericardium, and manifesting no disposition to collapse. No pleuritic adhesions existed on either side of the chest; nor was there any effusion, except into the right pleural cavity, which contained about three ounces of sanguinolent rather turbid serum.

A little recent pleuritis was found on the middle lobe of the right lung, rendering it slightly adherent by plastic effusion to the adjoining limbs to a small extent. Both lungs presented general vesicular emphysema to a very great degree, and their edges were more rounded than natural.

The larynx was not examined.

The lining membrane of the trachea and larger bronchi was smooth, but of a dark purple hue, from congestion in the minute blood-vessels: the same appearances extended throughout the bronchial ramifications, the smaller of which were filled with a very tenacious puriform mucus; and many of them were observed much dilated. Both lungs were extremely congested with dark blood, especially in and near the central portions of their lobes. At the superior and posterior part of the right lung was a small depressed and somewhat contracted surface, about the extent of a sixpence; a section of which exposed a calcareous mass, very uneven upon its surface, and about equal to the size of a small pea: it was placed about three lines distant from the pleura.

When the pericardium was opened, the heart was seen, very large and distended; and about two ounces of rather dark or brown-coloured slightly turbid serum occupied the posterior part of the cavity.

The right auricle and ventricle filled with very dark-coloured imperfectly-coagulated blood. The auriculo-ventricular valves sound. Through one of the pulmonary valves, near its angle of union with an adjoining valve, was a perforation nearly the size of a small goose-quill. A tolerably firm fibrinous coagulum was found in the

* Sir Astley Cooper wore a truss on the right inguinal canal, from the age of 19 to 25.

pulmonary artery and its branches, extending, by minute prolongations, to the fifth divisions; these were made evident, by withdrawing them in a continuous mass with the forceps.

The left auricle and ventricle were occupied by a large quantity of black grumous half-liquid blood. A large portion of the mitral valve opaque, and a little thickened; otherwise healthy. The aortic valves thickened, and rather rigid at their attached margins; whilst the free margins presented a remarkably healthy appearance for their age.

The left ventricle was much dilated; its apex much broader, and more prolonged than natural: the parietes somewhat hypertrophied; and the muscular fibres of the whole organ were pale, flabby, and weak.

The aorta, which was small and narrow, pursued its usual course, but gave off the left vertebral artery between the left common carotid and left subclavian. The entrance to the arteria innominata was contracted, and slightly irregular.

Many small irregular yellowish opaque patches were seen under the lining membrane of the thoracic aorta and the ascending portion of the left subclavian artery. In most of the parts so affected, the internal membrane was much softened, breaking down under slight pressure: at three or four points it was destroyed to a small extent, admitting a thin layer of dark matter, probably altered blood, separating it in a slight degree from the subjacent tissue: this latter state was noticed near the origin of the arteria innominata and the commencement of the descending aorta. The whole length of the abdominal aorta was full of black grumous blood; its parietes thickened; the lining membrane opaque, and raised by the sub-deposition of hard, almost bony matter.

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN IN LONDON AND ITS VICINITY.

THE half-yearly General Court of this Society was very numerously attended on Wednesday evening, at the Gray's Inn Coffee House; Sir Charles M. Clarke, Bart. in the Chair. As the private business of the Society was transacted, and the names of the pensioners mentioned, our reporter was requested to withdraw; but we learn from a gentleman present, that His Grace the Duke of Sutherland presented a donation of 20 guineas, and was elected a Vice-Patron; and that His Royal Highness the Duke of Cambridge had graciously consented to preside at the Annual Dinner on the 17th inst. These announcements were most cordially

received, and the respectful thanks of the Society were voted to His Royal Highness and to the noble Duke.

MARYLEBONE INFIRMARY.

Dr. Mayo was, on Friday, the 26th ult., elected one of the physicians to the Marylebone Infirmary.

LECTURES ON THE PRINCIPLES AND PRACTICE OF PHYSIC.

Delivered at King's College, London.

By DR. WATSON.

LECTURE XXIX.

Apoplexy continued. Symptoms characterizing the apoplectic state. Pressure the ordinary physical cause. Hemiplegia. Affection of involuntary muscles. Anatomical characters. Situation of the clot of blood. Disease of the cerebral blood-vessels.

WE were engaged with the subject of apoplexy. I requested your particular attention to the threefold mode in which that fearful disorder has been observed to make its attack. In the first, the coma is sudden, and deep; the condition of the patient, thus struck in an instant senseless and motionless, warranting those epithets which the ancients applied to the victims of this disease, of *attoniti*, and *siderati*, as if they were thunder-stricken, or planet-stricken. In the second form of the attack, the earliest symptom is acute pain of the head, with sickness and faintness; the coma *supervening* usually in no long time. The third form is ushered in by sudden hemiplegia, which may or may not lead to loss of consciousness, or stupor. The cases which range themselves under the one or the other of these three forms of attack are called respectively by Dr. Abercrombie *apoplectic* cases; cases *not primarily apoplectic*; and *paralytic* cases: and so as you bear in mind what these terms really imply, they appear unobjectionable.

I next pointed out the classes of persons in whom an attack of apoplexy is chiefly to be apprehended: those, namely, in whose families that disease has been known to be

common: those who have large heads, thick necks, red faces, square shoulders, and a short stature; although persons of quite the opposite conformation are by no means exempt from it: and lastly, and above all, those who have passed the middle period of life, and are advancing towards old age: and more particularly is apoplexy to be apprehended in people of this description when they have already suffered what are called head symptoms; which symptoms have reference to the three great functions of the brain and nervous system; voluntary motion, sensation, and thought. Such symptoms consist, therefore, in slight and often transient paralytic affections, double vision, a dropping of one eyelid, occasional inarticulate speech, weakness perhaps of a single finger; headache, giddiness, unnatural sounds in the ears, numbness or tingling of the extremities, which last are all modifications of sensibility; some impairment of the intellect, marked, most commonly, by partial and strange defects of memory, and temporary confusion of thought. When several or any of these symptoms occur, and especially when they become habitual in persons in the decline of life, we have reason to dread the supervention of apoplexy; and to exhort and protect our patients against its ascertained exciting causes.

Symptoms characterizing the apoplectic condition.—When the apoplectic state is fully formed, in what manner soever the attack may have commenced, it is marked by most or all of the following circumstances. The patient lies totally unconscious as to all that is going on about him: he replies to no questions, he is unmoved by the cries and lamentations of his family; in fact, he does not hear them: his pulse is infrequent, often full, perhaps intermitting: his breathing is peculiar, being slow, sometimes interrupted or irregular, attended with snoring or stertor during *inspiration*, and a puffing

G

out of the cheeks, like the action of one who smokes a pipe, during expiration. Both these peculiarities are referable to the same principle, and both denote a profound insensibility to all external impressions. There is no longer any voluntary attempt to breathe, yet the involuntary movements of respiration subsist: the medulla oblongata still responds to the impressions which reach it from the lungs, still prompts contraction of the muscles that enlarge the capacity of the thorax; but the loose curtain of the palate, and the lips and cheeks, are passive: by the vibrations of the one the stertor is occasioned; the mouth is closed by the mere elasticity of the others, and the flaccid cheeks flap outwards with the explosion of the air, as it escapes when the chest again collapses. The countenance is frequently turgid, and livid; the blood which tinges it is already but half arterialized; the pupils are commonly contracted. The limbs lie motionless: either they are all absolutely palsied; or (what probably is often the case) the capacity of motion remaining, the *will* to move them is wanting. If you raise one of them it falls passively down again, when you leave hold of it, like a *dead* limb. Sometimes, however, they are rigid and stiff. Sometimes one is stiff, and the others limber. And sometimes one or more of them, or those of one side, tremble, or are distinctly convulsed. You find the patient is unable to swallow; if you put fluids into his mouth, they appear to choke him, or they run out again at the corners of his lips. His bowels are usually torpid; but if they act, the evacuations are passed in the bed without his knowledge or concern: his urine also flows involuntarily; or is retained in the distended bladder until it fairly *overflows*, and dribbles away perpetually.

When the attack terminates in death, that event is preceded, I believe in almost every case, by profuse perspiration, which bursts forth from every part of the surface, and is often cold and clammy. The pupils are sometimes at this period dilated: and I have more than once seen them of unequal size. The pulse becomes more frequent, the breathing more rare, and at last it ceases altogether.

Pressure the ordinary physical cause.—This state, so appalling and painful to look upon, but fortunately so devoid of suffering for the patient—this suspension of the functions of animal life—depends, we have reason to believe, upon *pressure* applied to the brain, the organ subservient to those functions.

That excess of pressure is a *vera causa* is obvious, and that it is adequate to the production of coma is capable of demonstrative proof. It is not enough to shew that they often exist together, for the coincidence

might be casual. Neither does their occasional disjunction, real or apparent, furnish any conclusive argument against the general proposition, that coma, in many and in most cases, is the result of pressure upon the encephalon.

Coma may exist without pressure. In other words, coma acknowledges *other* causes also, *besides* pressure. It is produced by many narcotic poisons; by the circulation of venous blood through the arteries. In these cases we have no proof of any compression of the cerebral substance.

The other disjunctive condition is much more puzzling, and has led some persons to question or deny the general proposition. Can there be unnatural pressure, yet no coma? It would seem so. Serum, pus, blood, have been met with in the brain, foreign matters have penetrated the cranium, and coma has not occurred.

The force of this difficulty is lessened by the consideration that foreign substances may be present within the skull, without occasioning any preternatural degree of pressure. We read of bullets being carried about for some time in the brain. In such instances it is probable that a portion of the contents of the skull was forced out at the time of the injury; or that coma has come on, and gone off again, in consequence of the gradual absorption of the cerebral matter to make room for the foreign body. The same explanation may be applied to the chronic accumulation of water within the cranium, and to the slow growth of tumors.

Farther, it is open to conjecture that it is not on every part of the brain that the same degree of pressure made, will produce the effect ascribed to it. It is stated in Mr. Mayo's Physiology, as the result of actual experiments on animals, that *lateral* pressure against the hemispheres of the brain produces no observable ill consequence; but that vertical pressure, pressure downwards, occasions stupor, which is attributable to the compression of the medulla oblongata. Now it is obvious that some injuries of the brain may tend more than others to cause pressure in that direction.

I confess that the difficulty is not wholly relieved by these considerations. But it is a difficulty which cannot invalidate the evidence of numerous facts that attest the agency of pressure, as, at least, one cause of coma. The presumption of such agency arises whenever coma immediately succeeds to pressure; and it is converted into certainty if, upon the removal of the pressure, the coma immediately departs. Now the annals of physic are full of instances of that kind. In experiments upon animals, stupor has been brought on, and made to cease, at the pleasure of the operator, by applying pressure to the exposed brain, and by remit-

ting that pressure. Nay, the experiment has been tried on the human brain itself. A man who had undergone the operation of trepanning, and had recovered, was in the habit of exhibiting himself for money in Paris, where Haller saw him. He suffered the spectators to make pressure upon his brain, where it was covered by the integuments only. This always put him into a state of coma or deep sleep; but sensibility and the power of voluntary motion returned at once when the pressure was taken off.

A most remarkable example of the occurrence of coma from pressure upon the brain, and of the removal of the coma by removing the pressure, was afforded by a patient who was in St. Thomas's Hospital under the care of Mr. Cline. Mr. Green, who was Mr. Cline's nephew, was in the habit of relating the case in his lectures here. It is quite pertinent to my present purpose. One of Mr. Cline's apprentices was visiting the dépôt at Deptford, and discovered there a man who had been for some time in a state of unconsciousness; and he had him removed to St. Thomas's. His main symptoms were apparent insensibility to all surrounding objects, and a total incapacity to make any communication to those about him; except that his attendants learned to infer, from certain instinctive movements or gestures, that he felt hunger, or thirst, or a want to relieve his bowels. His fingers were permanently bent towards the palm of the hand, and his eyes were turned upwards, so that the corneæ were completely concealed beneath the upper lids.

Upon examining this man's head, Mr. Cline found that there had been fracture with depression of one of the parietal bones. He trepanned that part, and elevated the bone. The patient seemed to feel the operation; and as soon as it was concluded, his eyes and fingers were restored to their natural position. On the evening of the same day, he sat up in bed, and though at first stupid and incoherent, soon became rational and well.

When he had entirely recovered his senses, it was ascertained that the last thing he remembered was his serving on board a vessel which made a capture off Minorca. He was wounded in the engagement, and carried afterwards to the hospital at Gibraltar. All this happened upwards of twelve months before the operation. So that one whole year of this patient's life was a complete blank, because, during that period, a little piece of bone was pressing upon his brain.

Cases of this kind show, very convincingly, the connexion that subsists between pressure on the brain and coma, and their relation to each other as cause and effect. The pressure and the coma begin together; the coma continues as long as the pressure continues; and

it ceases when the pressure is removed. The old definition of the *cause* of a morbid condition is completely satisfied. "*Præsens morbum facit, mutata mutat, sublata tollit.*"

From this digression—not altogether foreign to our subject—I return to the consideration of the pathology of apoplexy.

Hemiplegia.—If the patient recovers from the coma, he may live a few hours, or days, or he may live for many years. Sometimes, as the coma departs, all the natural functions are gradually restored; but much more commonly paralysis remains. You already know that it is apt to affect one moiety of the body only. If a line be drawn from the vertex to the perineum, dividing the body into two halves, which, as far as the exterior is concerned, are symmetrical, all the *voluntary* muscles that lie on one side will be found powerless; or if they are not *all* so, those which are palsied are situated on the same side of the line. And this state of things is called *hemiplegia*. *Paraplegia*, that condition in which all the parts below a transverse line are palsied, though it sometimes results from cerebral disease, is much more commonly the consequence of mischief in the spine.

Now, of this hemiplegia, when it is complete, there are several particulars worthy of your notice; and there are many things worthy of your notice when it is incomplete. But we will take one of these predicaments at a time. By complete hemiplegia I mean palsy of all the voluntary muscles of one side. The patient may *will* the motion of his leg, or arm, but they no longer obey the act of volition; if they are lifted by another, and then let go, they drop down like logs of wood. You will find that, in well-marked cases, the *intercostal* muscles of the palsied side do not contract. The muscles of the face, also, are some of them inert on the same side. I have known many persons who have thought that the muscles of the *face*, in hemiplegia, when they were affected at all, were affected on the opposite side of the body from that to which the palsied *limbs* belonged. But they never could have examined actual cases of hemiplegia with any attention. How the error arose I cannot tell, but I have known a professed anatomist make it. I guess that it has arisen from one of two causes. An anatomist who had not looked closely upon disease, would expect, and not unnaturally, that the face and limbs would be affected on opposite sides of the body; seeing that the nerves which supply the muscles of the face are given off above the place where those fasciculi of nervous matter which are called the anterior pyramids, decussate each other. And a vulgar observer, who was not an anatomist, would be apt to conclude that the side towards which the mouth was drawn

was the affected side: whereas it is just the reverse. The face is drawn to the healthy side, because the muscles on that side are no longer counteracted and balanced by the corresponding muscles of the palsied side. The *blank* half of the face is that which answers to the paralyzed limbs: on that side the patient cannot frown, or smile. He presents a singular spectacle, which I do not dwell upon now, because I shall return to it again when I have to speak of certain important varieties of *local palsy*. What I wish you to bear in mind at present is, that when the muscles of the face are affected in hemiplegia, the *rule* is, that they are palsied on the same side with the limbs. But there is no rule, they say, without an exception: certainly the exceptions to this rule are very uncommon. I have not had leisure to look over the records of the very many cases of this disease which my position as physician to a hospital has brought under my observation; but I do not recollect more than two exceptions; and one of them, as it happens, is now exhibited in the person of one of my patients in the Middlesex Hospital. Some of you have seen the woman. It is a well-marked exception: but in this instance the hemiplegia followed a blow on the head, and I suspect that a double injury was inflicted; that the palsy of the face results from mischief on one side of the brain, and the palsy of the limbs from mischief on the other. This I only conjecture; because the phenomenon is so rare*.

Then, again, with respect to the *tongue*: when put out beyond the lips, its point is commonly turned to one side. To which side? Why *towards* the palsied side. For what reason? Why because the muscles that protrude the tongue are powerless on that side, and in full vigour on the other. That half of the tongue which corresponds with the sound side is pushed farther out than the other half, and therefore the tongue bends to the other side. Such is the usual fact, and such the explanation of it. But there are more numerous exceptions to this than to the paralysis of the external facial muscles. Sometimes the tongue comes out straight; sometimes the patient cannot protrude it at all; and sometimes, even, it bends towards the sound side. But the *rule* is as I have stated it.

This also has been noticed of the tongue in such cases; that the patient has been able, after some effort, to thrust it suddenly out, and then has required a certain interval of time before he could do so again; as if the spent nervous power was slowly regenerated. With these different affections of the tongue,

the patient's speech is variously altered. His voice is thick, muttering, inarticulate, or unintelligible. Sometimes, even though he may be quite conscious and rational, he is unable to utter a syllable; and seems vexed at finding that his attempts to speak are fruitless.

Supposing the patient to recover, wholly or partially, from the paralysis, it is the *leg*, in nine cases out of ten, aye and in a much larger proportion than that, which recovers first and fastest: sooner and faster than the *arm*, I mean. And another fact, quite analogous to this, is, that when one of the extremities alone is affected with paralysis, it is, in nineteen cases out of twenty, the *arm* that is so affected. I give you again the *rules*; they are liable to occasional exceptions. The reasons that have been assigned in explanation of this curious circumstance I shall lay before you by and by; after I have had an opportunity of describing the morbid appearances met with in the brain in these cases.

This, then, is one way in which the hemiplegia may become, or be from the first, incomplete: viz. in *extent*. One limb may be powerless and the other strong. But the palsy may also be incomplete in *degree*. The patient may be able to move and use his limbs, but they are feeble. He cannot bend his fist firmly; or lift his arm beyond a certain height. Or his leg feels heavy to him, and trails a little behind as he walks: he is unable to stand upon that limb; or to plant his foot securely, or with the usual precision. In short, there are innumerable gradations of paralysis, from slight weakness of the affected muscles to perfect immobility.

Besides the *palsy*, there is often *anæsthesia* also. But this is by no means so constant a symptom as the paralysis. The function of sensation (wherefore I cannot tell) is less frequently abolished or perverted than the function of voluntary motion. When the sensibility is lost, or blunted, or any how modified, it is so, commonly, in the same parts that are affected with paralysis. But sometimes there is *anæsthesia*, and no palsy; and, more strange still, there has been sometimes *anæsthesia* of one side, and palsy of the other. As a general rule, the *anæsthesia* is less common, and less intense than the palsy; and is much sooner recovered from.

The mental faculties are, in some few instances, quite unharmed by the attack: too frequently, however, they suffer irreparable damage. Of many persons, a striking alteration is evident in the whole character and temper. The brave man has become timid; the prudent man foolish; the calm and cheerful man peevish and impatient. There is no longer the same power of attention, the same capacity for business, the same

* This patient died afterwards, at her own home; and no opportunity was given of inspecting the body.

clearness and comprehension of thought. And, whatever other changes may be observable, there are two ways, especially, in which the patient, after he has emerged from the coma, is very apt to be affected: viz. by a defection of memory, more or less partial; and by a peculiar tendency to emotion, especially the emotion of grief: he will weep for very slight causes, sometimes long after the attack of apoplexy has passed over. This is very curious. I should have stated before that the same readiness to shed tears, and to be immoderately affected by trifling causes of emotion, is sometimes noticed among the *precursory* symptoms of apoplexy.

Tracing these cases onwards still farther—such cases, I mean, as do not perfectly recover—we find that the palsied limb wastes: inaction of the muscles, according to the principle which I explained to you in a very early part of these lectures, leads to a lessened nutrition, and a consequent diminution of bulk: in one word, to atrophy. Sometimes, indeed, the size of the helpless limb is maintained, or even augmented, by the supervention of oedema. The motion of the blood in its veins is not aided by the play of its muscles, and the cellular tissue becomes infiltrated with serous liquid.

Again, these palsied limbs are usually colder than their fellows. This probably is owing to the diminished circulation of blood through the capillaries: there is not so much blood converted into venous from arterial; and less animal heat is developed. This has been observed even when the main artery of the part has beat as forcibly as in the corresponding part on the other side.

It is necessary to be aware that these palsied parts do not resist the influence of cold or heat so well as the sound parts. When the sensibility is blunted, we can readily understand how the limb may become burned, from the absence of any warning pain that an injurious degree of heat is applied: but this is not all. A lower degree of temperature than would injure a sound part has often been found prejudicial to a palsied part: and if these palsied parts get chilled by frost, they more readily vesicate and inflame, on the return of heat, than other parts: merely *warm* water will sometimes act upon them like *scalding* water. I say a knowledge of this fact is of practical moment. That degree of warmth which the palsied limb fails to generate for itself, we must accumulate for it by warm clothing; and we must take care that it is never exposed to any artificial temperature which exceeds a certain point. We sometimes see mischief done by applying hot bottles or bricks—*too hot*—to such limbs.

In speaking of the palsy, I have dwelt especially on the loss of action and power observed in the *voluntary* muscles: but the

strictly *involuntary* muscles do not altogether or always escape. The pulse, as I have stated, will often become slow or irregular in the apoplectic attack; and the bowels are usually very obstinately costive; their peristaltic motion, which results from the contraction of involuntary muscles, is suspended or diminished. Now the old writers on apoplexy puzzled themselves with devising explanations of the fact that the involuntary muscles are so little affected in this disease. Boerhaave, and others, fancied that the voluntary muscles were influenced by affections of the cerebellum; the involuntary by those of the cerebrum, of the brain proper: but this is quite in opposition to well-ascertained facts. Le Gallois entertained the notion that the movements of the heart and alimentary canal are under the dominion, not of the brain, but of the spinal cord; and this doctrine was received and sanctioned by the French Institute: but it has been refuted by the experiments of later observers. We are enabled, I think, to explain, now a days, why the muscles of involuntary motion often are *not* affected in apoplexy. I have before had occasion to shew you that the functions of organic life are not necessarily dependant upon any influence derived from the brain: they might go on, if a due supply of arterial blood were kept up, even though there was no brain at all. Some fœtuses have arrived, in other respects, at their full growth, in which there was no brain; nay, in which there was neither brain nor spinal marrow.

In truth it seems to be more difficult to explain why the organs of involuntary motion *are* sometimes affected, in apoplectic and paralytic diseases, than why, in general, they are *not*. But some elucidation of this matter I have also attempted to give in a former part of the course. The organs of involuntary motion are not dependant upon the brain and nervous system; yet they are liable to be influenced through their medium; as we know by the effect produced upon those organs by certain emotions of mind. Dr. Wilson Philip has shewn clearly, by his experiments, that the way to affect the action of the heart, and of the involuntary muscles, through the brain and nervous system, is to act upon a *large portion* of that system at once. Hence any *disease* which inflicts extensive damage upon the encephalon will be likely to disturb and weaken the functions of the heart and alimentary canal.

Conversely, when we find, in a case of apoplexy, the involuntary muscles sensibly affected, we may infer, I believe, that the injury done to the nervous matter is great and serious.

Anatomical characters.—Let us next, with the view of farther explaining the pathology of this disease, direct our attention

to the appearances which are met with after death in the most common forms of the complaint.

I shall pass over those cases in which no morbid condition is detected, simply reminding you that the altered relation of the venous to the arterial circulation in the brain may perhaps account for the symptoms, and for the extinction of life: or the altered velocity of the blood circulating in the brain may account for them: or, what is more probable still, a determination of blood towards the head, or a detention of blood in the head, sufficient, by tightening the full vessels, to occasion extraordinary pressure upon the nervous pulp, may account for them.

I pass over likewise those cases in which serum only is found effused beneath the arachnoid, or into the ventricles. A moderate quantity of serous fluid poured out rapidly during life would certainly occasion a degree of pressure adequate to the production of fatal coma. How the serum comes to be so effused, it is not always easy to say. Yet there is one condition of the blood-vessels of the brain which, when it can be proved to exist in a given case, is sufficient to account for the effusion. Any real or virtual retardation of the blood in the cerebral veins would lead to what is tantamount to dropsy, *there*, as well as in any other part of the body; and the intelligible causes of such retardation are known sometimes to be in operation.

But I wish to consider more particularly the appearances that are met with in the brain after death by *cerebral hæmorrhage*, which, after all, is the most common source of apoplectic and paralytic disorders.

In the first place (as I have more than once stated before) the popular notion that hæmorrhage is owing to the giving way of a considerable blood-vessel—although this notion seldom has reference to the brain, because the blood cannot reach the external surface of the body, and therefore does not strike the popular sense—I say this notion is more true of cerebral than of any other hæmorrhage. Much more true, especially, as regards the brain than as regards the lungs, to which latter organ the bursting of a blood-vessel is, in vulgar parlance, most commonly ascribed.

This comparative frequency of hæmorrhage from the actual rupture of vessels may, in some measure, be accounted for by their peculiarities of texture and relation. The blood-vessels distributed within the cranium are long and slender; excepting the sinuses, the coats of both arteries and veins are thinner and weaker than in other parts of the body: the middle tunic of the arteries has not more than one-half its ordinary thickness; and the outer or cellular coat is

of such extreme tenuity that doubts have been entertained concerning its existence. These vessels, moreover, are not protected, as elsewhere, by investing sheaths of cellular membrane, and receive but slight support from the soft and delicate substance by which they are immediately surrounded. They are likewise very subject to a particular form of disease, by which their natural fragility is much increased, and lying near to the heart, and in the primary direction of the blood as it is driven from the left ventricle, they have been thought especially liable to sustain the additional momentum arising from the more forcible contractions of that chamber; whether these are determined by occasional and transient causes, or depend upon permanent organic disease of the heart itself. On this point, however, I shall have something more to say hereafter.

Still there is no reason, I think, for doubting, that hæmorrhage by *exhalation* may take place, though rarely, from the free surface of the brain, or rather of its investing membranes. But the *rule* is, that it proceeds from the mechanical rupture of a blood-vessel.

In cerebral hæmorrhage, the blood may be effused in one or other of three different situations; viz. upon the external surface of the brain, *i. e.* upon or between the membranes; or into one or more of its ventricles; or into the very substance of the brain itself. In the two former situations it is sometimes, perhaps, poured out by exhalation; in the latter, which is infinitely the most common, it always proceeds from the rupture of one or more blood-vessels.

It is necessary to remember that even when blood is found spread over the surface, or distending the ventricles of the brain, it frequently has not been originally poured out in those situations. If the hæmorrhage into the substance of the brain be considerable in amount, the blood generally forces a passage, by laceration of the cerebral tissue, either into the ventricles, or (less frequently) to the surface; or even in both these directions at once.

In some rare cases blood is found effused beneath or into the pia mater, over a small space only, as between one or two of the convolutions, and nowhere else. Sometimes it is spread in a thin layer over the whole of one hemisphere, and is found no where else. Sometimes blood is discovered in one or more of the ventricles, and no where else: but all these are comparatively unfrequent events.

When the blood is effused into the substance of the brain, and does not break a passage out, either in one direction or the other, its pressure is not necessarily or immediately mortal. The patient, as I have already explained, may survive for

weeks, or months, or years; and the clot of blood will, in the meantime, undergo very remarkable changes.

The cell, or cavity, in which the extravasated blood is contained, varies much as to its *size*. It is sometimes scarcely of sufficient capacity to receive a large pea: sometimes it occupies nearly the whole of one hemisphere. It is seldom, however, I repeat, that a communication is not formed between the original cavity and the surface in the one direction, or the ventricles in the other, when *much* blood has been shed. Frequently a direct opening is made by the blood from one lateral ventricle to the other through the septum lucidum; sometimes it passes from the one to the other through the foramen of Monro; and even the chamber of the septum lucidum itself has been found distended by a certain quantity of blood.

If the clot of blood in an isolated cavity be examined soon after its effusion, it is found to be of a soft gelatinous consistence, and of a dark colour, much like black currant jelly; the sides of the cavity are irregular and ragged; and the cerebral substance of which they are formed is generally, to the depth of a line or two, moist, soft, and as if stained of a reddish or yellowish colour, which is fainter in proportion as it is more distant from the coagulum, and gradually loses itself in the natural tint of the surrounding parts. This latter condition would seem to depend upon a slow imbibition of the serous portion of the effused blood mixed with some of its colouring matter. It begins to manifest itself about the third day from the attack, and is most apparent from the eighth to the twelfth day; at which period, under ordinary circumstances, the whole of the serum has been removed, and the process of absorption seems to be in active operation. By degrees this stain disappears; the coagulum becomes more and more compact; assumes first a brownish, and subsequently a pale red or even yellowish hue; diminishes continually in magnitude; and at length may be entirely reabsorbed.

In the meantime the walls of the cavity are becoming less uneven, and clothe themselves, by degrees, as they contract upon the shrinking coagulum, with a distinct membrane of a yellowish colour, sometimes of extreme delicacy, and resembling the serous membranes; sometimes thick, and apparently fibrous. When the opposite sides of the cell at length meet, they adhere together, and a true cicatrix ensues, the place of which is marked by a sort of fibrous knot, forming a remarkable contrast with the softer texture around it; or less frequently by a similar induration of a *linear* form. In this case, the sides of the collapsed cavity are sometimes found to be merely applied to each other, without actual adhesion. When, from the great extent of

the original cavity, or from some other cause, its parietes are not ultimately brought into mutual contact, there remains a kind of *cyst*, lined by a smooth yellowish membrane; sometimes traversed by a few slender threads of cellular tissue which cross each other in various directions; sometimes filled with a soft, fine, orange-coloured spongy tissue, in which a number of minute blood-vessels ramify; sometimes containing a gelatinous or serous liquid; and sometimes apparently empty, having been occupied by some kind of aeriform fluid.

It is impossible to assign the precise period within which these remarkable changes may be accomplished. Dr. Abercrombie has detailed an instance in which a coagulum, that must have been of very considerable size, had entirely disappeared in less than five months. In another of his cases it was seen to be partially absorbed at the end of three months. "On the other hand, Moulin found a small coagulum not quite gone at the end of a year; and Riobé observed some of the blood still remaining in a cavity of small extent after twenty months. In two cases Serres found a hard coagulum of blood remaining; in the one at the end of two, and in the other at the end of three years.

It has been said that the cicatrization of the cavity takes place much more slowly and imperfectly when the effused blood has passed *across*, and *torn*, the *fibres* of the brain, than when it has been poured out in a direction *parallel* to those fibres, so as to separate without breaking them.

Dr. Abercrombie states that he had never seen any thing to satisfy him that the cysts are capable of being obliterated by cicatrization. Neither have I. But Dr. Sims, Dr. Bright, and several of the French pathologists of approved credit and accuracy, agree in their description of this obliteration of the cells. And you should bear in mind that a small cicatrix in the brain may very easily escape notice, if not expressly sought for; especially as the examination of that organ is often conducted, viz. by cutting away thick slices from the hemispheres in rapid succession, in order to arrive as soon as possible at the lateral ventricles, and the base of the brain.

It frequently happens that a patient has suffered, during life, several distinct attacks of apoplexy or of cerebral hæmorrhage; and that as many cells are met with after death; exhibiting respectively various stages of that process of repair which has just been described.

These are the changes that mostly take place in the coagulum, and its containing cell, when the hæmorrhage does not prove fatal, and the patient recovers more or less completely. But the same changes do not always, or necessarily, occur. Instead of being gradually removed by absorption, the

extravasated blood appears occasionally to become a solid, organized, and consequently living mass, deriving its nourishment from the arteries of the brain. A man, whose case is related by Andral, was smitten with apoplexy, and remained thenceforward, for many years, hemiplegic. At length he died, of some other complaint, in the wards of La Charité. When his brain was examined there was found, in one of the hemispheres, a mass of a pale red colour and fibrous appearance, traversed by numerous small blood-vessels which anastomosed with those of the brain: the surrounding nervous matter retained its natural aspect; and there was no appearance of any cyst.

Situation of the hæmorrhage.—It has long been known that hæmorrhage does not occur in all parts of the *substance* of the brain indifferently. Morgagni had remarked the frequency of sanguineous effusions in or near the corpora striata and optic thalami; and more extensive subsequent research has amply verified the general correctness of his observation. Rochoux, in the treatise on apoplexy which I mentioned before, published in 1814, has given a tabular account of the morbid appearances observed by himself in the heads of 41 persons, dead after attacks of cerebral hæmorrhage.

In so many as 24 of these, *i. e.* in three-fifths of the whole number, the blood was extravasated in the corpus striatum; in two others in the optic thalamus; in one it was effused into the substance of both the corpus striatum and the optic thalamus of the same side; and in another, beneath the corpus striatum: so that altogether there were 28 cases out of 41, or seven-tenths of the whole number, in which the clot was confined to the corpora striata, optic thalami, and their immediate neighbourhood. In the remaining three-tenths the blood was found collected in several other parts of the cerebral mass; five times in the middle of one of the hemispheres; twice towards the posterior part of the ventricles; twice in the inner and *anterior*, and three times in the inner and *posterior* portion of the hemispheres; and once in the middle lobe.

In Andral's *Pathological Anatomy* you will find a much more extensive table relating to the same subject, and constructed by him from various authentic sources. It leads to the same general conclusions. Thus, among 392 cases of hæmorrhage into the nervous substance, there were 202 (or more than one-half) in which the blood was extravasated at once into the corpora striata, the optic thalami, and that part of the hemispheres of the brain which is on a level with those bodies. In 61 cases (or about one-seventh of the whole number) it was confined to the corpus striatum. In 35 (or one-eleventh of the whole) it was limited to

the optic thalamus; making, in all, 298 instances (or more than three-fourths of the whole number) in which the sanguineous effusion occupied the corpora striata, optic thalami, and their immediate vicinity.

The result of my own observation coincides entirely with this, although I cannot, at present, reduce it to a numerical statement.

From the same table we may infer also the comparative infrequency of hæmorrhage into the cerebellum. It is mentioned as having occurred in 21 of the 392 cases; or in about 1 in 19.

Dr. Craigie states that the parts which are the seat of the hæmorrhage may be arranged, in the order of frequency, as follows:—the corpus striatum; the optic thalamus; the hemispheres; the pons Varolii; the crura of the brain; the medulla oblongata; and the cerebellum.

It is natural to seek for some physical explanation of the cause which determines the extravasation of blood in certain parts of the brain more frequently than in others. Some light may, perhaps, be thrown upon this inquiry, by a consideration of the sources of the hæmorrhage, in the various forms of its occurrence.

I stated before that the blood *may sometimes* be poured out by *exhalation*, in those less frequent forms of cerebral hæmorrhage to which M. Serres has applied the term *meningeal apoplexy*, and in which the blood is found distending the ventricles, or spread, like a cap, over the surface of the hemispheres, without any laceration of the cerebral matter. This supposition rests, however, rather upon the analogy drawn from what is known to occur in other parts of the body, than upon any decisive and unequivocal evidence. Blood has not unfrequently been discovered in each of these situations, when the most careful scrutiny has failed to trace its source to any ruptured vessel. Yet we cannot doubt that such rupture may have existed—either in some one or more of the numerous vessels of the pia mater, in the one case, or of the plexus choroides in the other—and yet have escaped detection by the most vigilant eye. In Dr. Abercrombie's book there are two interesting examples of extravasation upon the surface of the brain, without any obvious source of the hæmorrhage; the one detailed by Dr. Hunter, of Edinburgh, the other by Dr. Barlow, of Bath.

That the hæmorrhage proceeds from rupture of some of the vessels composing the choroid plexus, rather than from the membrane that lines the inner surface of the ventricles, when the effused blood is confined to those cavities, is the more probable, because the vessels have been actually found broken (as in cases of ventricular hæmorrhage, described by De Haen and Cruveilhier), and because they are liable to well-marked

disease of a nature to render them more than usually fragile. The arteries, for example, which belong to that plexus, are subject to a peculiar kind of alteration that I shall presently mention, as frequently prevailing the whole arterial system of the brain; and its veins are often partially enlarged and varicose. This latter condition has sometimes been mistaken for a collection of small hydatids.

But hæmorrhage into the *substance of the brain* depends *always* upon rupture of some one or more of its blood-vessels; and it is to this fact of the rupture of vessels that we must chiefly look for an explanation of the peculiar liability to hæmorrhage of certain portions of the brain; the corpora striata, namely, the optic thalami, and the parts immediately adjacent to these. The corpora striata are not only of much softer consistence than most other parts of the brain, but they are also traversed by more numerous as well as by larger blood-vessels than are other parts. These facts, and the conclusions to which they point, did not escape the sagacity of Morgagni. "On some occasions (says he) when I have cut the corpora striata into pieces horizontally, I remember to have observed in the external anterior part of each, a little pit as it were, across which lay a very conspicuous blood-vessel. And on other occasions, upon cutting obliquely and slowly, I have remarked in the same situation many red lines, like threads, which were in fact blood-vessels running parallel to one another, and of a larger size than elsewhere." In truth you may often notice the open mouths of a cluster of such vessels that have been divided. Morgagni saw in this anatomical fact a probable solution of the pathological fact that the parts in question are the most common seats of extravasation. In corroboration of these views it is worth remarking that the corpora striata are especially subject to laceration and sanguine effusion, while the surrounding parts remain unhurt, in violent concussion of the brain. And when injections are forced into the cerebral blood-vessels in the dead body, it is in the very same parts, the corpora striata above all others, that a sort of factitious hæmorrhage is produced by the rupture of vessels, and the escape of their contents.

Disease of the cerebral blood-vessels.—I have mentioned some original peculiarities of texture and relation, which may be thought to predispose the blood-vessels of the brain, more than others, to laceration. But the *main* predisposing cause of that event is, doubtless, their great liability to *disease*. Except the commencing portion of the aorta itself, there are no arteries in the body so frequently found in a morbid state as the *cerebral* arteries. And the change to which they are most subject is that deposi-

tion, between their tunics, sometimes of a substance resembling albumen or soft cartilage, sometimes of actual phosphate of lime, to which we commonly apply the term *ossification*. This earthy or cartilaginous deposit exists usually in whitish patches of a roundish or oblong form, disposed at various distances from each other: sometimes in a succession of bony rings, with healthier portions of the artery between them. One effect of this morbid condition is to diminish the *bore* of the affected artery, and to make it of unequal capacity. And as this variation of calibre impedes the free passage of the blood, it tends indirectly to increase the pressure of that fluid against the sides of the vessel. Another effect is to deprive the coats of the artery of their natural elasticity, and to diminish their power of cohesion: and thus to render them weak and frangible, and at length unable to sustain the increased impulse of the blood. This condition occurs in the smaller ramifications as well in the larger trunks of the cerebral arteries.

There is yet another occasional cause of hæmorrhage. The arteries at the base of the brain are subject to *aneurism*, and to consequent rupture. Morgagni has reported cases of aneurism affecting the internal carotid and basilar arteries. Serres has described a case of apoplexy resulting from perforation of the basilar artery, which was dilated, not far from its superior bifurcation, into an aneurismal pouch as big as a hen's egg. Dr. Baillie records an instance where both the internal carotids, on the side of the sella turcica, were distended into little aneurisms, one of the aneurisms being about the size of a cherry, the other somewhat smaller: and similar examples are related by other writers. I have seen two such myself; and a beautiful preparation of one of them is preserved in the museum of the College of Physicians.

CLINICAL LECTURES,

By DR. CORRIGAN,

*Delivered at the Hardwicke Fever Hospital,
Dublin,*

During the Session, 1840-41.

LECTURE IV.—(FEVER, No. 2.)

WE occupied our preceding lecture with some general observations on fever, that were, I believe, absolutely necessary, previously to going into a description of fever as we see it at present under our immediate observation. I purpose now directing your attention to the characters of the fever at present epidemic, whether those characters serve to distinguish the disease, to serve as prognostic signs, or to be our guides in treatment.

Fever, as now in our hospital, naturally divides itself into three forms, and these are so well marked that we might almost call them classes. In one bed you see a representative of the first class—an approach to the simple inflammatory fever of Cullen. A patient is admitted on the second or third day of fever; the skin is hot; the pulse is quick and full; the tongue is creamy, soft, and white; the countenance is florid; and the skin, with considerable heat, gives a feeling of very slight moisture to the hand of the observer: a few rose-coloured maculæ are on the skin. This case, or the class of cases of which this is a representative, you might, perhaps, at first, suppose, from the vehemence of the symptoms, would proceed to still greater intensity, and would prove to be fever of great severity and considerable duration. It is, however, not so. These cases you will observe almost invariably turn out well, scarcely requiring any beyond the commonest attention. They terminate in a few days (seven or eight), either by gentle and continued diaphoresis, or seem quietly to go off without any marked crisis.

The maculated fever, however, as it prevails now, and has prevailed for some months, admits of a division into two forms; one, where the disease sets in with a heavy congestive stage, resembling almost the cold stage of ague; the other, where the onset of the fever is so gradual, that it seems to attack, as it were, by treachery; it seems hard, or sometimes impossible, to say at what precise moment the fever has commenced. The cases of two brothers, Herberts, just discharged cured, and the case of the woman Harrington, not yet out of danger, are good examples of the first form. One of the brothers, Herberts, presented himself at the hospital gate for admission immediately on his falling ill: he walked from his work to hospital. It would not be easy to forget his aspect: he was a stout-built man, and had been previously strong, yet he seemed, as it were, at once knocked down by the onset of the fever. He was chilled and sunken; his face anxious; his eyes slightly congested and drowsy; and his lips livid, or bluish; his pulse quick, and weak, and small. It is a singular circumstance that about ten days after his admission, his brother, who had been in England, and without any communication with him, was admitted immediately after he landed from the packet, into the hospital, with a fever of exactly the same character. Perhaps we may venture to explain this circumstance thus:—that members of the same family, having similar conformations and similar constitutions, are naturally liable to suffer in a similar way from epidemic influences; and thus brothers and sisters may, without any communication with each other, present fevers of similar characters. Perhaps

it may more often arise from this cause than is supposed, that several of a family will suffer from fever; and this similarity of constitution may often be the cause of fever attacking many of a family, when contagion has wrongfully been charged with the whole blame. We see an illustration of this same principle occasionally in children: when children of a family, separated from one another, will almost simultaneously catch whooping-cough, or other epidemic diseases. Popular observation says this has happened because the disease has run in the blood: the explanation appears to be that already given. The children of the one family resemble one another more in constitution than strangers; the constitution of the one child has felt the influence of the prevailing epidemic agent: there is nothing difficult to imagine in supposing that a similar constitution at some distance should bow to the same influence; and thus, perhaps, in those cases, as in the case of the brothers, Herberts, the same influence produced in similar constitutions the same results.

This form of maculated fever is always severe; reaction does not follow; the maculæ are all through the disease thick and dark-coloured, but well marked, although very dark in colour; the patient, even when crisis is going forwards, never loses the aspect of a person suffering under heavy congestion; convalescence is extremely slow, and returning strength a long time coming round.

The second form of the maculated fever is what may be called “*par excellence*” treacherous fever. It is a form that, were it only for your own character, you should remember: the first deviation from health is scarcely perceptible; the patient is for many days what he calls merely ailing; continues at his profession or business perhaps up to the moment of his sending for professional advice, or only remains in bed, and seeks for advice on the sixth or seventh day of his fever, or of the duration of his ailing, in compliance either with the urgent solicitations of his relatives, who see there is something wrong about him, or because he feels, as he describes himself, weak, and without appetite, and disinclined to leave the bed, even although he feels tired of it, and attributes the pains which he describes when questioned as flying down his limbs, as arising from his remaining in bed. When you see such a patient, there is apparently little to excite alarm. There is no complaint of pain except of trifling pains down the limbs; there is perhaps no headache; the pulse is not more than 88, and the tongue is only slightly coated; yet, as surely as such a case presents itself, will that case be a severe case, and one in a few days perhaps where life will hang by a mere thread. Did not experience tell us of the danger, of the severity of the class of which this is a slight

sketch, we could never anticipate that ultimately the danger would be so urgent. Such a case as this will perhaps go on with little change or little aggravation to the ninth or tenth day, when the patient rather suddenly becomes delirious, and either almost comatose, but still without sleep, or, what is worse, becomes exceedingly wakeful and restless; the whole nervous system continues in one uninterrupted state of agitation, resembling delirium tremens; the pulse rises in frequency, and sinks in strength, and the case is an accumulation of the worst symptoms of typhoid fever.

Let us, however, go back on one of those cases of insidious typhoid fever: I wish to impress, if I can, its picture on you, because its features are not so strongly marked, but that, if not well fixed in your memory, they may readily escape your detection. The greater number of cases of typhoid fever coming to our wards are of this class; so that there is no difficulty in your making yourself familiar with their aspect. The nature of the symptoms coincides with what we have already observed of the pathology of this fever. There is no local disease, nor local symptom of any intensity or urgency, but there is not a vital function that is not affected; trifling, it is true, in degree, as far as each may be concerned, but when the total is considered, and it is recollected that all are more or less affected, it is scarcely to be wondered at that in the course of a few days the result of the whole should be so overpowering on the system. The symptoms which point this out also diagnose this form of fever, and therefore I shall go over them a little in detail. I am now, recollect, describing the fever when it is most useful to recognize it—when, as I have already said, there is as yet to an inexperienced eye little, or rather nothing, to indicate the danger that is hanging over the patient. Care and attention in observing will, however, prevent any mistake. The patient's muscular and nervous strength is greatly reduced, so that he feels as weak as a child—as he often truly expresses himself. The same want of strength is exhibited in the countenance, which is dusky and anxious and heavy, with an eye often slightly congested, but still with no great heaviness over it. The cerebral system is also disturbed in its functions; there is no sleep, or it is unrefreshing and uneasy. There is perhaps nothing at this stage at all remarkable in the respiration, but the circulation is always a little quicker than natural, sometimes very little; perhaps the pulse beats only 88, but the next day it is 92, the day after 98, and so it goes on gradually rising: there is no sign of local disease to account for, or correspond with, this daily increase of pulse; and as surely as the pulse proceeds

in this way rising from day to day, there is danger preparing to burst. There is nothing to attract attention in the state of the bowels; the evacuations are perhaps natural, and the abdomen is soft. At first sight the tongue perhaps too seems natural, or very little altered: but if it be not dry, or even slightly brown in colour, it is of a grey colour, not with a creamy grey or white mucous coat, such as is presented in inflammatory fever, as already noticed, but without a fur or mucous coat, as if the villousities of cuticle on its surface were dyed of that colour. The patient, at this stage of fever, keeps his mouth generally closed, and breathes through his nose, so that he preserves the tongue somewhat moist; but even then pass your finger over its surface, and it gives you the feeling of not secreting any moisture on its surface, and your eye, if you look close, will detect the same. The patient replies, and the nurse often hastens with glee in such a case to tell you, that he has no thirst, that he does not call for drink; and this is often taken for a favourable sign of the fever being mild: for no other reason, I suppose, than that in inflammatory fever, there being great thirst when the fever is at its highest, it is supposed that when there is no thirst the fever cannot be dangerous. Experience, however, shows the conclusion to be ill founded: want of thirst is a still worse sign than want of appetite; it proceeds from the assimilating powers of the digestive organs being so completely arrested that there is not even the ordinary instinctive desire for drink; not even when the tongue is dry. I attach considerable value to the presence or absence of this sign; I have often foreseen the approach of aggravation of the case when the only warning symptom has been that absence of thirst, or cessation of desire for drink; and again anticipated a change for the better when the only sign to give me the information was return of thirst. The return of thirst, or desire for drink, tells us that assimilation is now going on, that the digestive organs are again taking up their duty, and the desire for drink is the instinctive calling for the supply thus required; as the absence of this instinctive calling had already told us that the digestive organs were arrested in their functions of assimilation. A little reflection will bear out, what experience tells us, that it is just as ridiculous to consider want of thirst a good sign, as it would be to consider want of appetite for solid food as a good sign. In fact, the want of desire for fluids shows a more extreme degree of the loss of the action of the digestive function, of which loss of appetite was the commencement. If you turn now your attention to the skin, it seems at first natural; but place your hand upon it, and although not hotter, perhaps, than natural, there is a dry biting

AN ESSAY

ON THE

SOURCES OF TYPHUS OR CONTINUED FEVERS.

BY JOSEPH BELL, Surgeon, Barrhead.

[For the Medical Gazette.]*

sensation given by it to the hand that is very disagreeable and very characteristic. It wants altogether the slightest approach even to that soft feeling that is conveyed even from skin much hotter. It is more like the extremely dry sensation given to the hand when laid on the side of a hot-air stove, than anything else I can compare it to; and which perhaps arises from its robbing the hand so quickly of its moisture: perhaps there is also some electric agency at work; but on this we can pronounce no opinion in our present state of knowledge. If the skin be more carefully examined by the eye, a few maculæ are detected about the epigastrium, abdomen, and loins: these are scattered, generally small and dusky, few, or in numbers so great as to give a mottled appearance to the skin, and yet so little different in colour as to require some care to discover them. They are sometimes mixed, even thus early, with the petechiæ of purpura. Various diagnostic signs are given to distinguish between them. This one is sufficient. Press the tip of your finger on the supposed stigma: if it be a petechia it will not disappear, for it is an effusion of blood, and cannot be pressed out of its place: if it be a stigma of fever, it is merely a congestion of a little circle of vessels, and the pressure of the finger will make the colour disappear—to return, however, in a moment again, after the pressure is taken off. The maculæ of a case of fever will sometimes present a very strong resemblance to the eruption of measles. We had a remarkable instance of this a few days ago in the female ward. All the peculiar distinguishing crescentic forms of measles were wanting. I notice the circumstance for two reasons: the first, to call your attention to the resemblance; the next, to fix on your minds the importance of what I am so often advocating, the advantage and facility of studying practical medicine by observation at the bed-side, instead of from books. All the distinctive signs of measles were recollected by you, and accurately given as you had learned them from books; but the most distinctive of all for some time escaped your observation, viz. that measles appear on the face, and maculæ of fever never do. The only remaining function I have now to notice is that of the kidneys. In the period of fever I am now describing, there are always some characters which indicate a departure from health. Indeed, I believe it is a secretion, giving us, by its changes, some of the most useful information in fever. It is often carelessly looked at, and described as natural, when the change is well marked and certain in its indications. To the characters of the urine we shall turn our attention in some of our succeeding lectures, begging of you, in the interval, to study it in the numerous opportunities that our fever wards now present.

A SOURCE of much ambiguity in all discussions, is the sense attached to the terms employed. This is well illustrated by writers on typhus fevers: scarcely two authors attach precisely the same meaning to this term. Many confound typhus fever with the typhoid state, which is, in reality, peculiar to no disease, and the attendant of many. "Typhus fever," observes a recent writer, "is not only an endemic disease *sui generis*, but so strong is the predisposition to that form of pyrexia, that it is prone to become an aggravation and superaddition to other forms of fever; and all the remittent types and degrees, as well as the catarrhal and peripneumonic fevers, are apt, either when long continued or improperly treated, under a heating regimen, to glide into it." Others, again, view typhus fever to be an exanthematous disease of a specific character. With this confusion existing regarding the nature of the disease, we cannot expect to arrive at a very satisfactory conclusion respecting the sources from which it originates, until we have a proper notion of what is really meant by typhus fever.

In order to prevent either ambiguity or confusion, I will state that I understand by typhus fever, that endemic disease, *sui generis*, by which our population is so frequently and so extensively affected;—disease which has a definite progress—succession of symptoms—has particular periods of increase and decrease: consequently the following inquiries will have reference to all those divisions of continued fevers adopted by writers on the subject.

Without entering upon any further preliminary remarks, we will at once proceed to examine the most prominent of the sources from which typhus fever is said to originate.

1st : *Contagion*.—I do not intend to trace the spread of fever from one individual to another: such a mode of investigation at best would only give

* This essay was read at a meeting of the Paisley Medical Society, March 2d, 1841.

rise to evidence of a very questionable nature. By taking a survey of our fever hospitals, I think we will be enabled to deduce a sufficiency of established facts to decide whether or not the disease be capable of being propagated by a contagious principle. In the elaborate report of Drs. Barker and Cheyne, on the fever which occurred in Ireland during the years 1817, 18, and 19, we find it stated that, "in the hospitals of the House of Industry, in Dublin, no clinical clerk or apothecary escaped an attack of the disease; and on the 20th January, 1819, it was reported to government that five of the medical attendants of the House of Industry were at that time lying ill of fever. In the city of Cork, nine physicians, in attendance either on dispensaries or fever hospitals, were attacked. Every medical attendant at the South Fever Asylum in that city suffered. At the hospitals of the House of Industry, 170 persons were employed in different offices of attendance on fever patients; and from this part of the establishment were recorded 198 cases of fever*."

These gentlemen state, that the ministers of the Gospel who visited patients labouring under fever during these epidemics, suffered in a very remarkable degree. Dr. Stokes, in his essay on Contagion, remarks, that "the deaths from fever recorded in Saunders' News Letter, from August 1st to December 12th following, are sixty-four, and of these nineteen are clergymen of some of the different persuasions, or of medical men of different descriptions; which appear greater than the proportion which these two classes bear to the whole of those whose deaths we may suppose were mentioned in that manner."

In Dr. Crampton's medical report of the department of Stevens' Hospital, we find it stated, that, "with the exception of Dr. Harvey and himself, all those concerned in attendance on patients caught the disease. None of the nurses, none of the barbers, porters, or those occupied in handling, washing, or attending on the sick, escaped, and many of them had relapses and recurrences of fever."

Dr. Roupell, in his essay on Typhus, gives a similar statement regarding the nurses attending patients in St. Bar-

tholomew's Hospital. He affirms that "among the nurses in attendance upon fever patients in that establishment infection was almost universal."

Dr. West, in his account of the fever cases that occurred in the same institution in 1837-8, states "that since last summer eleven gentlemen who were in the habit of frequenting the hospital have been attacked by the fever, to which three have fallen victims; sixteen nurses and twenty-one patients, admitted for other affections, have likewise suffered from the disease, which terminated fatally in ten instances; and I do not doubt but that similar cases occurred which did not come under my notice."

Dr. Tweedie, in his Clinical Illustrations of Fever, observes, at p. 87. "The London Fever Hospital is placed in an open space, situated in the vicinity of the metropolis, close to the Small-pox Hospital. Both these establishments stand in the centre of a large field, where the production of malaria is extremely improbable. I can state, from the most authentic sources, that every physician, with one exception, (the late Dr. Bateman) has been attacked with fever during his attendance, and that three of the eight physicians have died. The resident medical officers, matrons, porters, laundresses, and domestic servants, not connected with the wards, and every female who has ever performed the duties of a nurse, have one and all invariably been the subjects of fever. Last summer a most convincing illustration of contagion occurred. The present medical officer was attacked with fever, and it was necessary in consequence to appoint some one to perform his duties during his illness. The first person who officiated for him resided constantly in the house during the day, but took the precaution of sleeping at home. He was, of course, very much exposed in the wards during the performance of his duties. These, however, were soon interrupted by an attack of fever, which confined him for a considerable time. The duties were then taken by a medical pupil who had completed his education, and entered the hospital in the most robust health. He had been taught, and did implicitly believe in, the non-contagious nature of fever, and ridiculed the idea of any personal danger from residing in the hospital. He

* Barker and Cheyne, vol. i, p. 135.

performed the duty of house-surgeon for ten days only, when symptoms of fever appeared."

The same writer mentions several important circumstances respecting the fever which prevailed in the city of Edinburgh in 1817. He states that in the immediate neighbourhood of Queensbury House (which was then fitted up for the reception of fever patients) fever was decidedly less prevalent than in any other quarter of the town. All those, however, who resided in the hospital, including the resident house-surgeon, clerks, apothecary, nurses, were successively attacked."

Dr. Alison, in alluding to the same subject, in his report in the *Edinburgh Medical and Surgical Journal*, vol. xxviii. page 238, observes, "When Queensbury House was formerly occupied by fever patients, every resident clerk, and every nurse in the house, were successively affected with the disease; and since it was re-opened in Decemberlast, (1826) the resident physician, two of the clerks (who have not been resident, but have been several hours in the day in the house), the apothecary, several servants, and all the nurses, except two, in all about forty individuals, who had necessarily close intercourse with the sick there, have had fever. . . . During the present epidemic, (1827-8), as well as that of 1817-9, many of the clerks and nurses employed in the Royal Infirmary have taken fever. Since November last, six of the clerks employed in the clinical wards only, four of those employed in the ordinary wards, and twenty-five nurses or servants, have taken fever. All these persons had necessarily frequent and close intercourse with the fever patients in the house, having been employed more or less constantly in the fever wards, excepting four of the servants: of these four, two had been employed in the laundry, where the linen from the fever wards was washed. One was a porter employed at the gate, who would of course have communication with the fever patients at their entrance and dismissal, as well as their relations coming to visit them; and one was in the habit of visiting the fever wards. Not one of the nurses whose duty has confined them to the medical and surgical wards, where no fever patients were admitted, has taken fever, with

the single exception of the woman in the servants' wards above mentioned; and of the numerous patients in the ordinary wards, the only one who has taken fever within my knowledge during the present year, was a patient in the men's general clinical ward, who lay in the bed next the door that communicates with the fever clinical ward.

In the Fever Hospital of Waterford, Dr. Bracken tells us that "in 1818 there were twenty-seven attacks and relapses of fever among the nurses, servants, and porters, whose numbers fluctuated according to the demand for them, but who, on an average, may have been about twenty-two during the year." He also states that the year 1819 had a close resemblance to the preceding one in respect to the nurses and servants being attacked with fever, eighteen of the former having suffered under the disease; seven of them once, three twice, and one three times. The apothecary, who had not been long in the hospital, caught fever, and relapsed twice. During his illness, a young man who performed part of his duties was attacked after a short attendance. A temporary apothecary was then engaged for a few weeks; but he had not been many days in his new employment when he also contracted fever." In the tenth volume of the *Dublin Journal of Medical Science*, Dr. Mateer, of Belfast, gives a table of cases which were admitted into the Belfast Fever Hospital from the year 1818 to 1835, showing the number of patients who had either mediate or immediate communication with affected persons. It appears, from this table, that 7246 of the cases were clearly traceable to contagion, and the remainder, 2342, to other sources.

Dr. Cowan, in his pamphlet on the *Vital Statistics of Glasgow*, says that "all the gentlemen who have acted as clerks in the Glasgow Fever Hospital for many years past, have been attacked with fever, unless they had it previously to their election. During last year twenty-seven of the nurses of the establishment were seized with fever, and five of them died; several of the students have been affected. One gentleman, who acted as apothecary, died in the house; and if I have escaped, it must be attributed either to being past the period of life in which fever usually takes place, or to my being secured by having had two dangerous attacks at

an earlier period of my career, when acting as physician's clerk in the infirmary during the epidemic of 1816-17-18."

Dr. Davidson, in his recent prize essay, at p. 6, states that "in the Glasgow Royal Infirmary, which is capable of containing 220 patients, during the last six or seven years almost every clerk and nurse of the establishment have caught fever while acting in the wards. On the other hand, the nurses connected with the medical or surgical wards in the adjoining building have almost uniformly escaped."

I will not occupy your time by citing any other authority on the subject. The foregoing quotations afford sufficient facts for our purpose. It must inevitably follow, from these facts, that typhus fever is a contagious disease; and that contagion is a most prolific source of its origin. I say that such is the legitimate conclusion to which we must come, unless some fallacy be detected that overthrows this relation.

Let us, then, examine this matter with due caution and discrimination. In the first place I would observe, that the atmosphere of hospitals may be deteriorated by exhalations emanating from the congregation of patients, and from bad ventilation; and this may be the cause of the attacks of fever occurring in these hospitals. If fever originated from these sources, we would expect to find it occurring with the same degree of frequency in the medical and surgical wards of hospitals as in fever institutions. Human exhalations, and bad ventilation, exist even to a greater extent in the former than in the latter; and yet we find fever to be a rare occurrence in the former places. Hence, neither bad ventilation, nor emanations arising from the congregation of patients, can be received as a source of fever.

But in the second place I would observe, that the same cause which produces fever among the inhabitants of ill-ventilated and filthy places, may also exist in hospitals (namely malaria generated in large towns), and give rise to the disease among the inmates of an hospital. If this supposition were true, we would surely find this malarious principle exercising the same effect in the medical and surgical departments of our hospitals, as in the wards set apart for the reception of patients

labouring under fever. Such, however, we have seen not to be the case. Fever appears, indeed, to occur very seldom among either the patients or their attendants in the medical and surgical wards of hospitals.

There is still another circumstance which we must take into consideration before we can be justified in concluding that fever is contagious. Though it were proved that malaria be not generated in an hospital, yet this malaria may be conveyed there by means of the patient's clothing; and thus the attendants may be seized with the disease by coming in contact with them. Such an occurrence, however, is utterly impossible in the vast majority of fever hospitals. It is the rule, in these institutions, to remove the clothing from the patients, to put them into a bath, to shave their heads, and to give them clean linen, before they are admitted into the wards. This plan is adopted in the Glasgow Royal Infirmary; and Dr. Bracken tells us that the same regulation is observed at Waterford Hospital. This gentleman states "that according to one of the rules of that hospital, every patient has his hair cut at the time of his admission; he is also well washed with warm water and soap, and supplied with linen before he enters the sick ward."

Taking every thing into consideration, we are duly authorised to conclude from the facts before us, that contagion is a most fertile source of the typhus or continued fever of this country. Having established this point, let us in the next place ascertain if contagion be the sole source of fever; or if it be also originated by other causes.

If I were to adopt the mode of reasoning employed by Dr. Davidson, of Glasgow, in his recent essay, to which I have already alluded, the question would be soon settled. He contends, that if it be proved that fever is contagious, it must follow that it never originates from any other source. At page 2d he observes, "Some authors, apparently to get rid of the difficulty, and to account for the occurrence of typhus where no contagion could be traced, have adopted the opinion that it may be generated by common causes, such as impure air, filth, &c., and be afterwards capable of propagation by contagion. The argument of analogy is directly opposed to this belief; for

if, in nature, there be no exception to the law that two causes are never required to produce precisely the same effect, it will follow, that whatever cause can be best reconciled with the phenomena of typhus, must be considered the true source of the disease. But in order to apply this principle more immediately to the subject, it may be necessary to appeal to the various morbid poisons, the laws of which are known and generally admitted. The first we shall notice are those which are admitted by all writers to be propagated by one cause only, viz. matter, whether ponderable or imponderable, as the pus contained in a variolous pustule, or imponderable, as the effluvia issuing from a patient labouring under small-pox. Measles, scarlet-fever, hooping-cough, are propagated only by the effluvia which are generated by the patient. . . . Almost all the contagious diseases of the skin, such as syphilis, scabies, the yaws, &c. furnish examples of propagation by only one cause, viz. contagion. . . . If it be true, then, that all the contagious fevers known can be propagated only by contagious matter, and by no other cause—however much their contagious qualities, their prevalence, and their fatality, may be increased by other causes—it must follow from the law of analogy that if typhus can be proved to be contagious, it must also be propagated only by one cause, viz. contagion.”

I confess that I am very cautious in adopting either the statements or conclusions of a writer who asserts an opinion, and then brings forward facts and statements from all quarters in support of his views; while he either omits or explains away every circumstance which favours an opposite opinion. No person, indeed, however high his attainments, is qualified to investigate any subject, if he have not divested his mind of every preconceived opinion, and entered on the consideration of the subject in a truly eclectic manner.

Not to speak of the ambiguity of the above quotation, it displays a spirit very reprehensible, an animus totally opposed to all investigation and research, and highly injurious to the advancement of medicine. If we adopted his views, we must exclude ourselves from an investigation, “which, though

it should appear barren at present, may afford important results in some more advanced era of medical science.” His reasoning, however, is illogical; his arguments are perfectly futile. Unless he proves that the laws by which the operations of nature are governed are precisely analogous to those by which contagion is regulated—until he proves this, “the law of nature, viz. (that two causes are never required to produce the same effect), can have no reference to the question at issue.”

His second argument, though it possess more plausibility, is yet equally fallacious. It amounts to that species of sophism denominated *petitio principii*. It is not admitted that small-pox, measles, hooping-cough, scarlatina, and the skin affections, which he has placed in the same category, are never originated but by contagion. The instance of small-pox is perhaps more favourable to his opinion than that of the other diseases. With reference to measles, and still more to the others which he mentions, every experienced practitioner must have met with instances so apparently sporadic, that if his mind had not been prepossessed with the idea of contagion, he would never once have thought of attributing them to this source; and he must also have seen a number of cases of each of these diseases occur in a neighbourhood so simultaneously, as to exclude the supposition of contagion as a probable cause of their appearance*. But even admitting that these contagious diseases were never originated but from contagion, and admitting their analogy to typhus fever, it does not follow that the latter is only propagated by contagion, unless we have facts to substantiate the conclusion; much less if facts exist to favour a contrary inference. But does there exist any real analogy between the other contagious febrile diseases and typhus? I am inclined to think that, so far as we have facts to guide us, any analogy which may obtain is merely apparent.

Analogical reasoning at best is open to fallacy, and never ought to assume the place of facts. In medical investigations it is a source of great error; little reliance can be placed upon its evidence, owing to the state of our ig-

* Brit. and For. Med. Review.

norance respecting the laws by which diseases are originated and propagated. In such a state of knowledge we should receive with very great caution and discrimination any inference deduced from either apparent or slight analogies, which, I am convinced, occurs in the present instance.

The analogy is attempted to be proved by the following laws of exanthematous fevers:—

1. The contagion can be traced in families, hospitals, schools, &c.; and those exposed to it are generally infected.

2. They only affect persons once during their lives.

3. They are characterized by an eruption which has a rise, progress, and decline: and the disease cannot be checked *in limine*.

Do we find these laws prevailing in typhus fever?

With regard to the first law, it does not always hold good, even in exanthematous diseases. Many of these affections occur where no such connexion can be traced; and innumerable instances take place where persons escape the disease although exposed to the contagion. But even though this law were fully admitted, regarding both classes of disease, yet it would only prove that typhus fever was a contagious disease, not that it always originated from contagion.

2dly. Does typhus fever only affect persons once during their lives? The writer states himself, at p. 16, "that the evidence on which this law is founded in typhus, is by no means so clear and satisfactory as it is in exanthematæ." If such be the case, why then does he assume this alleged law as a fact, and argue from it, as such, that because typhus is analogous to exanthematæ in this particular, it cannot originate from any other source than contagion. Such a mode of reasoning, or of deducing general laws, is too absurd to merit comment, especially when many facts have been observed by competent authorities to prove the contrary. I have witnessed many instances of typhus occurring more than once.

3dly. Is typhus always characterized by an eruption which has a rise, progress, and decline, analogous to what occurs in exanthematæ? We will

adduce the proofs which the learned Dr. has brought forward on the subject. At p. 13 he states, "It was, however, observed by Rodgers, in the fever which prevailed in Ireland during the year 1731; and one of the characteristic symptoms is described as a *universal efflorescence of petechiæ*." Also by Huxham in 1734-5: Sir John Pringle in 1759, &c. No particular conclusions can be drawn from these authors' account of it! Farther, at p. 19, he states that "the typhoid eruption was also a very general characteristic of the epidemic fever which prevailed in Ireland during the years 1817-18-19." At p. 29 he states "that Dr. Alison described it as a very frequent symptom which prevailed in Edinburgh at that period." "M. Louis observed it in 25 cases out of 35; Chomel, out of 70 cases, in sixteen had no eruption; Roupell found it in 70 out of every 100 cases: Dr. West observed it in 42 cases out of 60: Dr. Cowan, in 2000 cases, found the average to be 73-99 out of every 100 admitted: Dr. Craigie saw it in 79 among 139 cases, in the Edinburgh Royal Infirmary; Dr. Henderson discovered it in 103 cases out of 130, in the same institution, at a subsequent period."

In the Glasgow Royal Infirmary, from May 1st to November 1st, 1839, out of 691 admissions, 250 had no eruption. If I may be allowed to quote my experience on the matter, I have found it in 45 out of every 100 of the cases of which I have notes.

Such, then, are the proofs adduced on this point. I would ask, is there any analogy between the frequency of the eruption, as proved here, and the appearance of the eruption peculiar to exanthematous diseases? not to speak of all want of evidence respecting the existence of regular periods of rise, progress, and decline of the typhoid eruption. That an eruption, a peculiar eruption, does frequently attend typhus, I frankly admit; but that this eruption occurs with such a degree of frequency and regularity as either to establish an analogy between the disease and exanthematæ, or to authorize the inference that, because the latter are never propagated except by contagion, the former must always arise from contagion, I am not prepared to allow.

With regard to the impossibility of checking typhus *in limine*, he does not adduce a single fact to prove this statement. It is true, he argues that those cases of fever said by some writers to have been checked in *limine*, may not have been cases of typhus; but this is no evidence either for or against his general law. He has fallen into the error common to many writers, of deducing positive conclusions from negative considerations. We are, therefore, justified in concluding that there exists no analogy between the two classes of disease, that authorizes the inference which Dr. Davidson would have us to adopt.

Typhus fever and exanthematæ are very dissimilar in many respects, and may they not also differ in this very particular—namely, that, though exanthematæ are never produced except by contagion, yet fever is frequently originated from other sources? A writer in the British and Foreign Medical Review observes on this subject, "Nor does it appear that there need be much hesitation in making the assumption, since it is so much in accordance with the convictions of many practical men of acute discernment." Dr. Bateman says, on the same subject, "We cannot doubt that a great number of the cases of fever which occur during an epidemic season, are entirely independent of contagion for their origin." Dr. Prichard observes that "instances are very numerous in which fever has arisen under circumstances almost precluding the possibility of an origin in contagion; and so many examples of this description have fallen under my own observation, as fully to persuade me that this disease does originate spontaneously, or independently of communication with any infected body." Dr. Percival, and a host of other practical observers, hold the same opinions.

It is my own conviction that not only typhus, but also many of the exanthematæ, arise sporadically, and become the centres from which the respective diseases are propagated. Such, at all events, must have been their origin at one period. To reconcile the opposite doctrine with experience, this contagious principle must have a kind of nature, and be occasionally for considerable periods shut up,

as a writer on the subject has expressed it, in "holes, chests, and caves, and has even for a time made its hiding-place in spiders' webs*."

[To be continued.]

OBSERVATIONS

ON

THE STRUCTURE OF THE GUBERNACULUM,

AND THE DESCENT OF THE TESTIS IN THE FÆTUS.

COMMUNICATED BY T. B. CURLING, Esq.

[For the Medical Gazette.]

DISSATISFIED with the description of the structure of the gubernaculum, and the causes of the descent of the testis, commonly given in English works on anatomy and physiology, I have recently made a careful examination of these parts, and conceiving that the results may be interesting to the younger members of the profession, I beg to forward the following observations to your journal for publication.

The chief facts ascertained by Mr. Hunter, in reference to the descent of the testicle, are so well known that it is needless to occupy space by repeating them here. Mr. Hunter observes, in regard to the structure of the gubernaculum, which is so intimately connected with this process, "It is hard to say what is the structure or composition of this ligament; it is certainly vascular and fibrous, and the fibres run in the direction of the ligament itself, which is covered by the fibres of the cremaster or musculus testis, placed immediately behind the peritoneum. This circumstance is not easily ascertained in the human subject, but is very evident in other animals; more especially in those whose testicles remain in the cavity of the abdomen after the animal is full grown†." He adds, "In the human fœtus, while the testis is retained in the cavity of the abdomen, the cremaster is so slender, that I cannot trace it to my own satisfaction, either turning up towards the testis or turn-

* British and Foreign Medical Review.

† Works, with notes by Palmer, vol. iv. p. 7.

ing down towards the scrotum. Yet, from analogy, we may conclude that it passes up to the testicle, since in the adult we find it inserted or lost on the lower part of the tunica vaginalis, in the same manner as in the adult quadruped."

Sir Astley Cooper states that the gubernaculum "is composed of several strong ligamentous fibres, which proceed through the inguinal canal to the cellular membrane of the scrotum, in which it is lost*." He also remarks, "The cremaster, as far as I can distinguish it in the fœtus, passes upon the gubernaculum to the epididymis and testis, and is attached to the process of peritoneum, which descends with the testis as a pouch, to the lower part of the inguinal canal; and the testis descends into this muscle as into a purse, as it is directed down by the gubernaculum, and hence the loops which it forms."

From these passages it will be seen that Mr. Hunter and Sir Astley Cooper described the gubernaculum as attached to or lost in the scrotum, but mentioned no other attachment. Mr. Hunter conceived that the fibres entering into the composition of this body were muscular, and identical with the cremaster—a conclusion at which he arrived chiefly from analogy, but which was not clearly established by anatomical observation in the human fœtus†. Sir Astley Cooper seems to have traced the fibres of the cremaster passing upon the gubernaculum to the testis, though not very distinctly. His meaning in the second quotation given above is somewhat obscure; but when the passage is considered in conjunction with fig. 3, in plate 9 of the same work, in which the testis is represented still in the abdomen, whilst the cremaster is seen surrounding the pouch of peritoneum in the inguinal canal, it would appear that he regarded the cremaster as forming a

pouch ready for the reception of the testis previous to its descent. He says nothing of the cremaster becoming everted, as obviously takes place in certain animals in the descent of the testicle, at the period of sexual excitement. Sir A. Cooper and Mr. Hunter both contended that the cremaster is not the cause of the descent of the testicle.

M. Jules Cloquet, whose description of the cremaster is now generally regarded as the best and most accurate, observes, "The cremaster does not exist before the period at which the descent of the testicle takes place; it is formed in proportion as this organ, which is drawn down by the gubernaculum, passes from the abdomen into the scrotum."* In a fœtus of not more than five or six months, he says, the fibres of the internal oblique are completely enclosed within the inguinal canal: "towards their middle they adhere somewhat closely to the gubernaculum; and when this part is drawn downwards, they are seen to descend with it through the external ring, forming successively curves, whose concavities are turned upwards, and which afterwards become developed upon the testis and the spermatic cord. The laxity of these inferior fibres facilitates their elongation, and finally their descent through the external ring. By drawing down the gubernaculum, we simulate in some degree the natural descent of the testis, and form an artificial cremaster."† M. Cloquet here adopts a somewhat similar view to that previously suggested by Carus,‡ viz. that the cremaster is formed during the progress of the testicular descent. It seems surprising that this excellent anatomist, who, it may be presumed, was not ignorant of the facts presented by comparative anatomy, should have arrived at a conclusion so incompatible with the relations and condition of this muscle in animals, in whom it is clear that no cause of a mechanical nature could thus operate in producing such an arrangement of the muscular fibres.

Having briefly stated the views commonly entertained and received in this

* Observations on the Structure and Diseases of the Testicle, p. 41.

† Mr. Owen, reasoning likewise from analogy, and looking upon the cremaster as a part too important to be formed accidentally, fully believes that this muscle exists as such in the human fœtus, prior to its descent, though he does not admit to have seen it at that period—See note to Palmer's edition of Hunter's Works, vol. iv. p. 8. It is but justice also to an excellent anatomist, Mr. Wilson, to mention that he observed the fibres of the cremaster running upwards on the surface of the gubernaculum—Lectures on the Urinary and Genital Organs, p. 162.

country, in regard to the structure of the gubernaculum and the descent of the testis, I proceed to relate the results of my own observations on this subject, in the examination of numerous fetuses at different periods of utero-gestation. For the opportunity of making these inquiries, I am indebted to the kindness of several medical friends.

The gubernaculum is a soft solid projecting body of a conical form, but which varies somewhat in shape and size at different stages of the testicular descent. It is situated in the abdomen, in front of the psoas muscle, to which it is connected by a reflection of peritoneum, which invests it in the same manner as this membrane surrounds the different abdominal viscera, the posterior and attached part at which the vessels enter being uncovered. The gubernaculum is connected above to the inferior extremity of the testicle* and to the lower end of the epididymis and commencement of the vas deferens. The lower part of this process passes out of the abdomen at the abdominal ring. On laying open the inguinal canal, the gubernaculum, which is further exposed, seems to diminish in substance, and to spread, but by a little careful dissection it may be found to terminate in three processes, each of which has a distinct attachment.

The central part and bulk of the gubernaculum is composed of a soft transparent gelatinous substance, which on examination in the microscope is found to consist of nucleated cells—the primitive cellular tissue. This central mass is surrounded by a layer of well-developed muscular fibres, which may be distinguished with the naked eye, and which can be very distinctly recognized in the microscope as fibres of animal life, by the appearance of the transverse striæ. These muscular fibres, which may be traced the whole way from the ring to the testis, are surrounded by a layer of the soft elements of the cellular tissue, similar to that composing the central mass, and the whole is invested, except

at the posterior part, by the peritoneum. On carefully laying open the inguinal canal, and gently drawing up the gubernaculum, the muscular fibres may be traced to the three processes, which are attached as follows. The external and broadest is connected to Poupart's ligament in the inguinal canal. The middle forms a lengthened band, which escapes at the external abdominal ring, and descends to the bottom of the scrotum, where it joins the dartos. The internal passes in the direction inwards, and has a firm attachment to the os pubis and sheath of the rectus muscle. Besides these, a number of muscular fibres are reflected from the internal oblique on the front of the gubernaculum. From this description the anatomist will at once perceive the similarity between the attachments of the muscle of the gubernaculum, and those of the cremaster in the adult. I have succeeded in tracing out the attachments of the former before the testicle has descended, at different stages of the process, and immediately after its completion, when the fibres have assumed the relations of the cremaster muscle; and of the identity of the two no doubt can I think continue to be entertained. In the descent of the testis, the gubernaculum, including its peritoneal investment and muscular fibres, undergoes the same change as that which takes place in certain of the *rodentia* at the access of the season of sexual excitement. The muscle of the testis is gradually everted, until, when the transition is completed, it forms a muscular envelope external to the process of peritoneum which surrounds the gland and the front of the cord. At this period the fibres connected with the remains of the gubernaculum can easily be demonstrated to correspond with the cremaster. As the testicle approaches the ring and scrotum, the gubernaculum diminishes in size, owing to a change in the disposition of its cellular elements. The muscular fibres, however, undergo little or no diminution, and are very distinct around the tunica vaginalis in the recently descended testis. The mass composing the central part of the gubernaculum, which is so soft, lax, and yielding, as in every way to facilitate these changes, becomes gradually diffused, and after the arrival of the testicle in the scrotum contributes to form the loose cellular

* Every anatomist is aware that the inferior extremity of the testis of an adult is not invested by the tunica vaginalis, which membrane is reflected from the gland at a distance of about five lines, the point being marked by a white and rather irregular line. This uncovered portion of the testis corresponds to the original attachment of the gubernaculum.

tissue which afterwards exists so abundantly in this part. The middle attachment of the gubernaculum, which may be traced to the dartos at the bottom of the scrotum, gradually wastes away, and soon becomes indistinct. Slight traces, however, of this attachment often remain to the latest period of life. After death, in dragging the testicle of an adult out of the scrotum by pulling the cord, the lower part of the gland, which is uncovered by serous membrane, is often found connected to the bottom of the scrotum by a band of firm and dense cellular tissue, which requires division with the scalpel in order to complete the separation. I believe this band to be the remains of the middle attachment of the gubernaculum. In boys, whose testicles are retracted by the action of the cremaster muscle, little pits or indentations may sometimes be noticed at the bottom of the scrotum, occasioned by the integuments at that part being drawn up in company with the testicles. When the testis is restrained in the groin, a cord of dense cellular tissue, the remains of this process of the gubernaculum, may occasionally be traced from the gland to the lower part of the scrotum.

It has been seen that Mr. Hunter, though disposed to believe that the cremaster passes up to the testicle whilst in the abdomen, nevertheless came to the conclusion that this muscle is not the cause of its descent. It is difficult to understand why, after arriving at the former conviction chiefly from analogy, he was not induced by the same process of reasoning to conclude that a muscle capable of drawing down the testicle in animals would be adequate to accomplish the same purpose in the fœtus. The necessity for some active agent to effect this change in the latter, would appear to be greater even than in animals, since, in the usual position of the fœtus in utero, the passage of the testicle is contrary to gravitation, and unaided by the movements of respiration. Now when we consider the attachments and connections of this muscle in the fœtus, the perfect condition of its fibres, as ascertained by microscopical examination, and the circumstance that there are no other means, no other motive powers, by which this change can be effected, or in any way promoted, I see no reason to question

that the cremaster discharges the same office in the human embryo as that which it undoubtedly performs in certain animals at a particular season. The fibres proceeding from Poupart's ligament, and the obliquus internus, tend to guide the gland into the inguinal canal; those attached to the os pubis to draw it below the abdominal ring; and the process descending to the scrotum to direct it to its final destination. As the descent approaches completion, the muscular fibres, which perform so important a part in it, gradually become everted, assume new relations, invest the gland, and instead of drawing down the testicle, acquire the new functions of elevating, supporting, and compressing it.

After the preceding observations had been put on paper, I was led to consult the writings of some of the continental authors on the subject of the descent of the testis. In works, evidently little known, and rarely referred to by English writers, whose leaves remained uncut in the libraries of the College of Surgeons and Medico-Chirurgical Society, I found much interesting information, and not only a fuller and more satisfactory account of the gubernaculum and testicular descent than is to be met with in anatomical works of recent date in this country, but that many of the points which I had myself remarked were previously noticed by these writers. The authors whose works I have chiefly examined are Palletta,* Brugnoli,† and Seiler;‡ and their observations, particularly those of the two latter, are certainly well deserving the careful perusal of scientific anatomists. Brugnoli, who wrote in 1785, but a few years after Mr. Hunter, described the attachment of the gubernaculum to the os pubis, and distinctly recognised the existence of the cremaster in the fœtus; as will appear from the following passages. "*A testis extremitate inferiori corpus quoddam pyramidale cujus basis erat superior, apex inferior, versus inguen pergebat, ut, disiectis fibris, partim in Fallopii ligamentum et musculi obliqui interni inferiorem oram, partim, superato obliqui externi*

* *Nova Gubernaculi Testis Hunteriani et Tunice Vaginalis Descriptio*, &c. Edit. Sandifort 1788, but originally published in 1777.

† *De testium in fœtu positu*, &c. Edit. Sandifort, 1788, but first published in 1785.

‡ *Observationes nonnullae de testiculorum ex abdomini in scrotum descensu*, Lipsiæ 1817.

annulo, in ossium pubis latera, et scroti (quod ea ætate vix ullum est) imam partem se insereret.* "Albus autem stipatus, et planiusculus ille funiculus, diversus omnino a cellulari commune, qui uno fere filamento in os pubis superius, duobus vero, tribusve in inferius os implantatur, nil aliud, ut opinor, est, quam fasciculus aliquis carnosus ipsius cremasteris a pubis osse ortus, vel quædam tendineae fibræ a femoris vagina aberrantes."† Brugnoli also correctly described the gradual eversion of the gubernaculum and cremaster in the descent of the testis.‡ Sceler gives the following account of the gubernaculum. "Hæc vagina parvum ligamentum conicum (gubernaculum Hunteri) includit tela cellulosa spissa formatum, quod in apice plicæ vaginæ illius, ubi testiculi et epididymitis inferiores apices se tangunt, incipit, descendendo fit crassior, per anulum abdominalem transit, in duos tenues se dividit ramulos, quorum unus cum tela cellulosa se coniungit, quæ ante anulum abdominalem aponeuroticam expansionem tegit, alter gracilior adhuc versus symphysis ossium pubis cum tela cellulosa spissiore se commiscet. Si involucrem illud a peritonæo formatum vaginam ante levamus, musculares fibras detegimus, quæ a musculo abdominali obliquo interno et transverso sursum se incurvant, massam illam cellulosam obducunt et cum illo coherent ita, ut ligamentum gubernaculum Hunteri, maxima saltem ex parte, tendinosa illarum fibrarum muscularium productio esse videatur, transitus enim telæ cellulosæ in membranosa serosam et tendinosam compagem, est fere inobservabilis."|| These observations are illustrated by a well-executed engraving, in which the fibres reflected from the internal oblique to the gubernaculum are distinctly represented. Sceler remarks, "Cremasterem constituent fibræ illæ musculares, gubernaculum Hunteri obducunt, quæ augentur et amplificatur."¶

After giving a minute and accurate description of the cremaster in the rat, and others of the Rodentia, and of the descent of the testis in these animals

during the season of sexual excitement, this intelligent author asks, "Si vero in his animalibus talem exercent functionem, cur illis non similem in embryonibus humanis concedamus actionem, ubi similem invenimus structuram?"* I might quote many other passages full of interest and information; but enough has been adduced to call attention to the labours of these neglected authors. Meckel, a more recent writer, whose Manual of Anatomy has always maintained a high repute, described the gubernaculum as commencing at the upper part of the scrotum, and receiving fibres from the internal oblique and transversalis, which, becoming everted in the descent of the testis, form the cremaster muscle. He appeared to be unaware of, or not to admit, the connection of the gubernaculum to the pubis, and the process extending to the bottom of the scrotum, and he consequently came to the same conclusion as Dr. Hunter—that the muscular fibres are insufficient to bring the testis lower down than the abdominal ring and complete the descent, the cause of which he regarded as unknown.†

I have been chiefly induced to bring forward the foregoing observations, in order to correct the wrong impression in respect to the cremaster, which it appears has been made in this country by the work of a French anatomist of considerable reputation, M. Jules Cloquet (*Recherches Anatomiques sur les Hernies de l'Abdomen*).‡ I have no hesitation in declaring that the views of this writer on the formation of the cremaster, as quoted above, which have evidently been adopted by many British anatomists§ without due examination,

* Ibid. p. 37.

† Manuel d'Anatomie générale, descriptive et pathologique, tr. par Jourdan et Breschet, tom. iii. p. 670, et seq.

‡ This work has been made more extensively available to English students by the excellent translation of my friend, Mr. McWhinnie, of St. Bartholomew's Hospital, who offers, however, no objection to the views of his author on the formation of the cremaster.

§ Mr. Harrison, in speaking of the cremaster, observes: "This muscle is probably formed incidentally, the testis, in its descent to the scrotum, carrying before it the lower border of the internal oblique (Dublin Dissector, 5th edit. p. 838, p. 143.) Mr. Quain's account of the cremaster strictly agrees with that of M. Cloquet. He believes that it does not exist before birth, and describes the gubernaculum merely as a fibro-cellulose cord, which extends down through the inguinal canal to the external surface of the pubic symphysis. (Elements of Anatomy, 4th edit. 1837;

are erroneous and inaccurate, and moreover, inconsistent not only with the original and exact observations of Mr. Hunter, but also with the subsequent investigations of Brugnoli, Sciler, and other continental anatomists, and, I may add, with my own inquiries, as detailed in this paper.

March 25th, 1841.

ON HIP DISEASE AND LUMBAR ABSCESS.

By WM. OLIVER CHALK, Esq.

Resident Surgeon to the Royal Sea-Bathing
Infirmary, Margate.

Of Psoas Abscess.

THE symptoms which characterize this disorder may be divided into three stages. In the first we have flattening of the nates, apparent lengthening of the limb, canting of the pelvis, and dragging of the extremity as in the early periods of hip disease, originating in a like cause, that of giving rest. The gait is uncertain, accompanied by frequent stumbling. If the patient be desirous of picking up any thing from the ground, the limb is thrown behind, the sound one flexed, and the body bent forward: in this way any pressure on the psoas muscle of the side affected is avoided. Now this is altogether different from the manner (already described) in which the same object would be obtained by one suffering under morbus coxae. There is more or less languor after exertion, dull pain in the loins (not, however, invariably present), occasional pains along the limbs, chiefly confined to the knee, especially at night and in the recumbent posture: they are at first erratic, but afterwards become fixed in that articulation. The latter symptoms are peculiarly diagnostic of this disorder, particularly the pain at night. The patient, when lying, rests the limb on the sound one, the knee is bent, and the thigh is flexed on the pelvis. In the erect posture the extremity is thrown forward, and the toe is scarcely

allowed to touch the ground: by this means the knee is bent, and the thigh partially flexed on the pelvis. The position adopted in both instances is obviously the one most calculated to relax the psoas muscle, and to maintain it in a state of quietude. The rest is broken, accompanied by occasional moanings and startings: these symptoms become more constant and distressing as the disease advances. If the patient be now submitted to a careful examination, by making pressure in the lumbar region on the side of the spine of the limb affected, or be placed in a supine position, and the abdominal muscles relaxed by flexing the thighs on the pelvis, and the psoas muscle be examined through the parietes of the abdomen, we may succeed in discovering a tenderness of the parts. At this time it will occasionally happen that a slight projection of one or more of the vertebrae may be observed, but this is not necessarily the case: for should it proceed from caries the bodies may not as yet have undergone sufficient change to produce curvature; besides which, depositions of tubercular matter in the loose cellular tissue surrounding the psoas muscle (constituting psoas abscess) constantly take place, independent of any spinal affection. Yet it should always be borne in mind that accumulations of pus in this situation do give rise to it: so that the spinal affection may be cause or effect.

The duration of the symptoms already described, constituting the first stage, is very uncertain; it may be confined to weeks, months, or even to years, (obeying the laws which regulate depositions of serofulous or tubercular matter in other structures of the human frame), depending entirely upon the state of the patient's general health, unless suddenly developed under the influence of a local injury superadded to the original mischief. The following case is an instance in which the primary symptoms extended throughout a period of nearly six years.

John White, a delicate boy, æt. 11, admitted July 1st, 1838. He states that about five years since he fell whilst at play; immediately afterwards he complained of weakness and of occasional slight pain in the right hip and groin. About twelve months afterwards he began to experience darting sensations in the hip and knee, more especially at

pp. 381 and 877.) Mr. Morton, in a useful work just published (*The Surgical Anatomy of Inguinal Hernia, the Testis, and its Coverings*), quotes Cloquet's description of the cremaster, and fully adopts his view of its formation. (p. 231 and 269)

bed-time: these have continued up to the present time. The spine is curved laterally, he is pigeon-breasted, the buttocks on both sides are of equal fulness; locomotion is unimpaired. He complains of great pain on pressure at the pit of the stomach; the tongue is furred, bowels irregular, pulse quick; he suffers from slight thirst. The hepatic treatment was adopted, and he underwent a course of bathing, beginning with the warm salt-water bath three times a week, which was afterwards followed by the douche, warm and cold, applied along the course of the spine at similar intervals. By these means his general health and strength were greatly improved, the pains in the hip and groin, together with the spinal and thoracic deformity, were much relieved. He was discharged October 12th. He returned to the Infirmary June 18th, 1839, much in the same state as when he left in the previous autumn, except that he had acquired a limping gait, and walked with a stick. There was also a slight recurrence of the hepatic symptoms. A similar medical treatment was now pursued, together with the warm salt-water bath. His general health and strength improved as before. Just previous to his departure (October 8th) I observed a fulness on the upper and outer side of the thigh, which yielded an obscure feeling of fluctuation. The swelling continued to increase during the winter, and he suffered much pain in the hip and knee. Any attempt at motion caused great uneasiness. He was again admitted as an in-door patient, May 29th, 1840. The abscess, which had increased to a considerable size, broke the day previous to his admission, and about a pint and a half of thin straw-coloured fluid, mixed with the usual tuberculous matter, escaped from a very small opening low down on the outer side of the thigh. The discharge was profuse for several weeks, but gradually abated. The general treatment consisted in a careful regulation of the bowels by mild aperients and enemata of warm water, together with tonics, and a generous diet of wine, ale, &c. The local applications were, ointment of the iodide of mercury applied over the walls of the abscess, with gentle support by a circular bandage applied daily. Ioduretted lo-

tions, and poultices of bread and Ext. Conii, were used whenever the abscess became painful and irritable. He was allowed to move about on crutches, when he could do so without exciting too much pain. By these means the abscess was nearly healed at the time of his departure (Oct. 12), and his general health was excellent. I have just now had an opportunity of examining the patient, and a small cicatrix is all that remains of a once formidable disease. The knee is slightly contracted, and the muscles of the hip have not yet recovered their power, as he is unable to flex the thigh on the pelvis, except by the aid of his hand, but he suffers no pain from so doing. He walks with a stick and crutch. The spine is quite straight, and the thoracic deformity has disappeared. His general health has continued excellent.

I have just now observed that the symptoms of psoas abscess are divisible into three stages, but I should not consider such a division at all necessary, were it not that by so doing I am enabled to point out more particularly a circumstance peculiarly diagnostic of the disorder, and one which will often serve to clear up our doubts when we are called upon to treat it in the latter stage, where it is often so very difficult to determine whether the hip or the psoas muscle be the original seat of the mischief. During the time that pus is accumulating in, and remains confined to this muscle, pain in the hip, knee, &c. must be present in a greater or less degree, according to the extent of the abscess; but no sooner does it acquire sufficient size to gravitate, quit the pelvis, and form on the inner side of the thigh, (or, as is very commonly the case, follow more directly the course of the psoas muscles, and occupy the interspaces of the muscles of the hip-joint,) than the pain in the hip, knee, &c. ceases for a while. The reason of this is obvious: the lumbar nerves now are no longer compressed and irritated, as when the matter was confined to the body of the psoas muscle. This symptom is so constant in lumbar affections that it seems to me of sufficient importance to constitute the second stage. The following case is one in which, from this circumstance alone, I was enabled to establish the diagnosis:—Edward Peel, *ætat.* 8, was

admitted as an out-door patient, August 16, 1833, from one of the London hospitals. It was stated by the person in whose house he was placed, that he was convalescent from hip disease, and that a slight weakness of the limb, together with general debility, was all that remained of the disorder. On examining the hip, I found the integuments covered with the cicatrices of leeches, blisters, &c.; and I learnt that, for some months previous, he had suffered severe pains about the hip, knee, and along the limb, more especially at night, and whenever in the recumbent posture. It did not appear that the topical remedies, though often repeated, had been productive of relief, but that suddenly, and not long before his arrival at the Infirmary, the pain had ceased. I carefully examined the spine, and found one of the lumbar vertebræ slightly projecting, it afterwards became more prominent as the disease advanced. He was discharged at the closing of the house, on October 30th following, much in the same state as when he came. He did not, however, return home, and I determined on watching the case, directing the party who had charge of him to let me know immediately if any swelling over the nates or in the groin should be observed. Not long after this I was requested to see him. A fluctuating tumor, about the size of a bantam's egg, just beneath Poupart's ligament, was now perceptible. I did not interfere with it, and merely prescribed some general treatment. The tumor increased to a considerable size, but did not cause much pain or inconvenience. He was allowed to move on crutches as usual. At the end of four or five weeks an opening was about to form, the integuments were inflamed, and beneath them could be seen the pus. I now made a small opening with a sharp pointed bistoury, the precise size of the inflamed skin, and liberated four ounces of straw-coloured fluid, with flakes of tuberculous matter. The discharge, after the first exit of the pus, never exceeded a table-spoonful in the twenty-four hours. The orifice soon after ulcerated to the size of a shilling. The after-treatment consisted in gentle compression by means of compresses and a bandage applied round the pelvis, and the application

of the ioduretted lotions to the walls of the abscess, and he recovered in the course of eight or nine weeks. I have heard of him several times since, and have been informed that he continues to enjoy an excellent state of health. I might here take the opportunity of relating many other cases bearing on this particular point, but I trust the foregoing one will be sufficient to indicate the importance of attending to the circumstance. The third stage of lumbar abscess may be considered that in which the suppurative process is fully completed, and an exit to the pus produced either by nature or by art. The soft fluctuating tumor of the nates, formed by the insinuation of pus among the interspaces of the muscles of the hip-joint, has often been confounded with dislocation of the head of the femur on the dorsum ilii. Some surgeons have gone so far as to say that psoas abscess may be distinguished from morbus coxæ from the circumstance of its pointing on the inner side of the thigh only. It would be fortunate if this were true, but the fact is the very reverse, for it commonly points and finds exit behind or near to the great trochanter; and even if it breaks in the groin in the first instance, the pus may subsequently burrow about the muscles of the hip, and form an outlet in the vicinity of the articulation.

The case of George Hastings, æt. 16, shewn in the accompanying woodcut, is an instance of such an occurrence. He was admitted May 12, 1836. He stated that he was a sailor, and that two years since he was occupied in scouring the deck without his shoes or stockings during a wet and cold day; three days after this he was seized with violent pains in the lumbar region, (these symptoms were accompanied by severe febrile action); in a fortnight they subsided, and he then began to complain of pain in the groin, which shortly extended to the hip and knee, and became more especially painful at night, and whenever in the recumbent posture. In attempting to rise suddenly, or after walking, he experienced an acute lancinating sensation in the hip and groin. — These symptoms subsided twelve months prior to the formation of the abscess, which formed a tumor of considerable size, and pointed in the groin

Case of George Hastings.

No. 1. Outlet to the abscess in the groin.

2. 4. Orifices to the abscess.

3. The site of an issue degenerated into a strumous ulcer.

(this happened in December 1835, eighteen months prior to the commencement of the disorder): nearly four ounces of pus were liberated: soon after this several outlets formed in the vicinity of the hip-joint, and discharged profusely. The limb was turned inwards, the knee contracted, and the thigh flexed on the pelvis. He suffered great pain in the hip, knee, and ankle, accompanied by irritative fever. The integuments were covered with the cicatrices of cuppings, leeches, and blisters, and an issue placed behind the great trochanter had degenerated into an irritable ulcer*. On pressing the abdomen in the lumbar region, pus issued freely from all the openings. The patient was altogether in a lamentable condition. It is unnecessary to detail the treatment, which extended over a period of some months. He only quitted his bed a fortnight previous to his departure from the Infirmary (Oct. 25th); and on his first rising it was observed that he had increased considerably in height: the circumstance was so obvious that I felt anxious to ascertain by admeasurement the precise increase, which, according to his own statement, was rather more than three inches. The discharge was now very slight, comparatively speaking, and from two orifices only: all the other wounds were healed. He could walk tolerably well on crutches, and the limb was less contracted. His general health was greatly improved; and a diarrhœa, from which he had been suffering at frequent intervals during

his stay, had now entirely subsided. I selected this case as the subject of a drawing, as it gives an excellent idea of the state of the parts when psoas abscess finds an exit in the vicinity of the articulation and exterior of the thigh.

The situation in which the abscess points would appear to be regulated by the quantity contained in the sac. If it be small it is usually in the groin, immediately beneath Poupart's ligament. It seems probable that the matter remains some time on the brim of the pelvis before an exit is formed, for I do not remember to have examined any patient who died of lumbar abscess, where caries to a greater or less extent was not observable at some part of it. When the accumulation is larger, it follows the course of the psoas muscle, and insinuates itself among the muscular interspaces of the hip and outer side of the thigh, and generally points behind the great trochanter, and in the vicinity of the articulation. If, however, it be very great, as is sometimes the case, it descends beneath the fascia of the thigh, producing great increase in the size, and fluctuation becomes perceptible in all parts of it. In this case various openings may form, both on the inner and outer side of the thigh, and about the hip-joint.

An abscess originally very small may give rise to one of great extent, by involving other parts in its descent. In the case of William Gibbard, æt. 20, admitted July 31, 1837, suffering under posterior curvature of the spine, and a scrofulous affection of the left knee-joint, and who died of enteritis the fol-

* The case had been treated as disease of the hip.

lowing September, I found, on a post-mortem inspection, that a slight caries of the bodies of the 3d and 4th dorsal vertebrae had given rise to an abscess, which had insinuated itself between the condensed cellular tissue at the side of the spine, descended along the psoas muscle, beneath the pelvic fascia, and through Poupart's ligament to the intermuscular space at the upper and inner part of the thigh: no opening had been formed during life. Upon a moderate computation the sac could not have contained less than a gallon and a half of pus.

Occasionally the abscess points in the lumbar region, at the side of the spine, and sometimes it does so after the matter has found an exit elsewhere. In two instances of this description, where the orifices sloughed, and the cases did badly, it was followed by hæmorrhage, which, although restrained for a time, ultimately proved fatal. In the case of W. H. Hilder, æt. 12, admitted July 14, 1835, [who was suffering from scrofulous abscess on the left side of the thorax, and from an accumulation of pus in the lumbar region, which was perceptible at the side of the spine, and formed a tumor of some size], just prior to his departure, Oct. 9th, the matter gravitated along the psoas muscle, and he began to experience pain in the hip and knee, while the swelling entirely disappeared. During the interval that took place between the time of his departure and return to the Infirmary, May 14, 1836, his case had been treated as hip disease. Two openings had formed in the vicinity of the articulation; one of them was situated behind the great trochanter: the discharge was profuse. The case went on badly, and ultimately the integuments sloughed, where a blister had been placed over the articulation, extending to the precise size and form of it. Nothing could exceed the suffering caused by this circumstance: he returned home Oct. 1st, in a hopeless state.

The position of the limb in psoas abscess is almost invariably the same: it is turned inwards, and rests on the sound one: the thigh is flexed on the pelvis, and the knee bent. I have only met with two instances to the contrary, and will take this opportunity of relating them, as they are by no means devoid of interest.

The first is that of Thomas Stapleton, æt. 14, admitted May 11, 1836. I was much struck by the position of the limb: the thigh was situated at right angles from the pelvis, the knee was flexed, and the patient lay on his face. I was at a loss, in the first instance, to account for this, never having had an opportunity of witnessing a similar case. There were two orifices, one on the upper and anterior part of the thigh, and another a little below the former, on the outer side. The discharge was not profuse, but it was unhealthy. On questioning him as to the cause of his position, he said that he was induced to adopt it in consequence of the pain he experienced when lying down. His general health was greatly impaired; he was suffering under hepatic symptoms, and from obstinate constipation of the bowels. The following is the history I gained from the patient:—He stated that on Sept. 3d, 1835, he was seized with sudden and severe pain along the whole course of the right lower extremity, since which time he had been entirely confined to his bed; and that for eighteen months previous to this, when taking violent exercise, such as running, &c. &c., he had been subject to occasional darting sensations along the limb, &c. The hepatic treatment was adopted, and the bowels carefully regulated. The febrile symptoms were allayed by a strict antiphlogistic treatment, and an amelioration of the symptoms ensued. He was afterwards placed on a tonic regimen. The discharge from the orifices diminished. The patient now complained of tenderness in the lumbar region, and a slight blush was observable on the integuments near to the posterior spine of the ilium. A circular bandage was passed round the thigh, and compresses of lint placed over each orifice. These soon healed, and an opening was formed Oct. 17th, where the integuments had become inflamed, and about half a pint of healthy pus was liberated. He suffered considerable constitutional irritation whilst the abscess was forming in this situation. He left the Infirmary Oct. 24th, greatly relieved in every respect.

John Lineham, æt. 28, admitted May 14th, 1836, suffering under lumbar abscess; this was excited by rheumatic action. He is a post-boy. He states

that about two years since he suffered from pains in the knee, more particularly at night. They continued increasing for a year and a half, and at last, becoming so violent that he could not lie down in bed, he adopted the expedient of placing himself at the side of it, letting the limb hang down; when, according to his statement, it became considerably enlarged (probably from œdema). There were several sinuses discharging profusely in the neighbourhood of the hip-joint. The limb was shortened to about four inches; the knee was much contracted. He left the Infirmary Oct. 24, the wounds for the most part healed, and his general health greatly improved.

[To be continued.]

ON ARTIFICIAL ANUS FOR RELIEF OF STRICTURE OF THE RECTUM.

To the Editor of the Medical Gazette.

SIR,

IN the account of *Cancer of the Rectum* in the *Cyclopædia of Surgery*, the following paragraph occurs:—"Surgery has yet another mode—in the establishment of an artificial anus—of relieving sufferers from obstructed rectum, and of warding off imminent death. There are, at least, seven cases on record, in which this operation has been performed on the adult subject, when every effort to relieve the distended bowels having been made in vain, symptoms of stercoral tympanites and strangulation, with momentary risk of rupture of the intestines, had set in. Five of these operations proved completely successful, and in one of the others the fatal event was mainly due to previous unskilful treatment: the operation is, therefore, warrantable in a surgical point of view."—(*Cyclopæd.* vol. i. p. 679.) A foot-note refers the reader to the *MEDICAL GAZETTE*, July 1840, for further information. This reference was made under the impression that a note on the subject, of which I intended to beg the insertion, would appear in your pages of that date. By some accident I mislaid the note, and, until recently, forgot the circumstance. As the point to which it refers is one of practical importance, I

shall feel much obliged if you will give it a place, as now enclosed, in one of your forthcoming numbers.

I am, sir,

Your obedient servant,
W. H. WALSHE, M.D.

Principal circumstances connected with seven cases, in which an Artificial Anus has been established in the adult for the relief of urgent symptoms produced by Stricture of the Rectum.

[1. FINE (An.?) *Vid. Odier, Man. de Médecine*, p. 274, ed. 2, 1811.]—Female, æt. 70. Symptoms of gangrene from fecal retention; tumor completely obliterating the rectum at its origin.

Opening made at "most prominent part of the abdomen;" one or two stools daily afterwards; patient lived more than a year, and died dropsical.

[2. PILLORE (1776). *Vid. L'Expérience*, Janvier 30, 1840].—Adult male. No stool for upwards of a month; not a particle of two pounds of mercury, which had been exhibited by the mouth, discharged. Eight or nine inches of the end of the colon and beginning of the rectum totally obstructed from schirrous induration, &c.

Transverse incision of the integuments above the fold of the right groin, and same of the cæcum; abundant fecal evacuation. Peritonitic symptoms on the 20th; death on the 28th day. The bowels had not been completely emptied; the exact original weight of mercury being found in a knuckle of the jejunum, behind the bladder.

[3. FREER (1817). *Vid. Med. and Phys. Journal*, vol. 45, p. 9, 1821.]—Male, æt. 47. Contraction of gut complete; attempt made to divide the stricture; no stool for ten days, vomiting, hiccup, &c.; "death inevitable."

Incision above and within anterior superior spine of the left ilium, and in descending colon; painful evacuation; patient, however, gradually sank, and died on the ninth day.

[4. PRING (1820). *Vid. Med. and Phys. Journal*, vol. 45, p. 1, 1821.]—Widow, æt. 64. Obstruction seven inches above the anus; total retention of feces for twelve days.

Incision within and above antero-superior spine of left ilium, and in descending colon: immediate and forcible discharge of feces. Three months

after, indurated fæces passed through the natural anus, and continued to do so. Six months after, the patient was in good health.

[5. MARTLAND (1824). *Edinb. Med. and Surg. Journ.* p. 271, 1825.]—Male, æt. 44. A large tumor protruding, as it were, from the neck of the bladder; no stool for twenty-six days; marked stercoral tympanites.

Incision an inch above and within antero-superior spine of the left ilium, and in descending colon; instant escape of fæces and flatus; a year after the patient enjoyed good health: soft stools passed on a few occasions at one period through the natural anus.

[6. AMUSSAT (1839). *Vid. Gazette Médicale*, Oct. 1839.]—Woman, æt. 48. No stool for upwards of twenty-six days; nausea, vomiting, &c. Hard, round, immoveable tumors, at the upper part of the rectum.

Incision in left lumbar region, and in descending colon. Four months after the operation, patient in excellent health: one or two evacuations daily: flatus passed by natural anus.

[7. AMUSSAT (1839). *Vid. same paper.*]—Case previously treated by breaking down fungous masses in the rectum, and subsequently by cauterization. Patient in a deplorable state.

Opening made in left lumbar region and in descending colon; no escape of fæces till the fifth day. Four months after, the patient in a better state than before the operation, and about to quit Paris for the country.

"When the disease is cancerous, the chances of ultimate advantage are, of course, vastly less than in cases of retention from simple induration; but even here it may be justifiably performed, provided the patient, after having been made fully acquainted with the nature and likelihood of the benefit to follow, still desire to undergo it." It is scarcely necessary to add, in defence of this position, that (even admitting the benefit obtained to be necessarily of short duration, which is by no means certain), there are cases wherein the preservation of a given life, even for a few days, may be of the utmost consequence to families, in a worldly point of view.

It will be observed that in Pillore's case the unfortunate issue probably depended on the obstruction caused by the gravitation of the mercury into the

pelvis: the site of the incision was also evidently ill-judged. The cause of death in Freer's case does not very clearly appear from his detail.

M. Amussat's motives for preferring the operation proposed by Callisen (the lumbar incision, whereby implication of the peritoneum is avoided) to the inguino-abdominal incision of Littre, are explained in his papers referred to.

ON WOUNDS OF THE FEMORAL VEIN IN OPERATIONS FOR ANEURISM.

To the Editor of the Medical Gazette.

SIR,

So much depends, for the satisfactory and successful performance of all important operations in surgery, upon the state of preparation of the mind of the operator for every possible emergency that may arise, and the possession of means calculated to remove the embarrassment which ensues, that I presume the following brief observations upon a melancholy occurrence, to which even the best surgeons are liable, may not be unacceptable:—

There cannot, perhaps, occur to the surgeon a more lamentable accident than an injury of the femoral vein at the time of applying a ligature to the femoral artery. Quiet, and unaffected by it, as the patient, at the time of its occurrence, appears, the practised surgeon beholds in this apparently trivial incident a sad calamity, fraught with the most certain, though not instant, destruction of his unhappy patient. As the most skilful* and experienced hands are liable to fall into this fatal error as well as the unskilful, and as "there is scarce an instance on record of the patient's recovery†," when it does happen it becomes the duty of the surgeon to devise, if possible, some means by which he may secure his patient from a danger of his own infliction, more sure to destroy, than the disease he is attempting to cure. Every recorded instance of this kind I have met with proved fatal. In the course of a few months I have seen it

* See *Lancet*, vol. 1, for 1828-9, a case by Sir A. Carlisle; and a paper on Phlebitis, by Mr. Arnott, in *Med.-Chir. Trans.* vol. 15; also Travers's *Surgical Essays*, part 1.

† Hargrave's *Operative Surgery*, p. 94.

twice happen in the hands of different individuals. The first patient died in consequence; the second was rescued by a measure to be presently stated.

That simple wounds of veins, both superficial and deep, properly treated, are unattended by danger, will, as a general rule, be acknowledged by all, I take for granted. It is proved by the result of superficial and deep wounds in phlebotomy, and amputation. I have seen, during the removal of a tumor deeply seated in the neck, the internal jugular vein wounded, and bleed profusely till the conclusion of the operation, when the parts being allowed to return to their natural state it immediately ceased, and caused no further annoyance; and I am of opinion that a simple incision of moderate extent in a vein, parallel to its course, will rarely produce trouble, provided the vessel remains undisturbed, the contiguous parts are brought into contact with it, and the member is placed in a motionless and favourable position. Even a transverse wound, unless the slit is very large, will, I doubt not, do best when left to itself. The practice of tying wounded veins has the support of excellent authority, and is occasionally done on the face of stumps with impunity, as I have repeatedly observed: yet I am quite satisfied it should always be avoided till all other means have failed to arrest the bleeding—an event almost always attainable by patience and judicious management. A wound of the femoral vein, caused in passing the aneurismal needle round the artery, scarcely bleeds, as I have witnessed on two occasions, unless the openings are dilated by the elevation of the needle or ligature. I have had repeated proofs of this in the operations already alluded to. Whenever the parts were elevated by the needle, or by the ligature, the blood freely flowed; but the instant they were allowed to subside, it ceased. In a case of this kind it must be borne in mind that we have a double wound in the coats of the vein: for it is transfixed by the needle; and if the ligature is passed and tied, a segment of its circle is enclosed within the noose. This appears to me to be the cause of the fatality attending this occurrence. The injury of the vein is succeeded at first by adhesive inflammation, which quickly closes the orifices, and, were

not the ligature there, would suffice for its cure. But in a few days this action is extended, through the incessant irritation of the foreign body, passes the limits of safety, proceeds along the lining membrane of the vein in the direction of the heart, and gives rise to the first symptoms of constitutional disturbance. The ulcerative process then begins, the parts immediately surrounding the noose slough, and that portion of vein within it is cast off, leaving an opening in the vessel, through which dark unhealthy blood mixed with pus escapes, and the patient speedily passes into an irremediable state of typhoid phlebitis.

From what we experience in other wounds of veins, we are justified in concluding that the ligature is the whole and sole cause of this fatal phlebitis. And I am of opinion, if the ligature in every instance of the kind that has happened had not been applied, but the parts been brought together and treated as a common wound, the deaths ascribed to this accident would never have occurred. The removal of the instrument leaves a double injury of the vein, consisting of two small orifices, their long diameters parallel with the venous trunk. I consider that a case of this kind, judiciously treated, presents nothing in itself necessarily dangerous. The inflammation of the vein, induced by the ligature, is the cause of death. Nothing, I am therefore convinced, will excuse the practice of allowing the ligature to be applied upon the artery at the part where the vein is injured; and I should regard myself, were this misfortune to occur under my hands, guilty of the most culpable malpractice if I applied the ligature at this part, and allowed it to remain. The practice I would adopt in such a case is, to open the sheath of the vessels an inch above the injury in the vein, and tie the artery there, provided there should appear sufficient space between the wound and the deep artery of the thigh, to justify its application; if not, to go the same distance, or more, below. If the aneurism is in a state which would admit of the necessary delay, it becomes an inquiry whether it might not be better practice to allow the wound entirely to heal before the artery is exposed a second time. The only recommendation this course ap-

pears to present is the entire cessation of inflammatory action it would admit of in the vein, before the possibility of fresh disturbance could arise from the ligature. On the other hand, we must bear in mind the effect of a failure and second operation on the patient. These are circumstances, however, which each individual case and operation must determine. Future experience may decide whether the safest plan would be to pursue the treatment I am about to mention, but at present I am not prepared to give it unqualified commendation.

In the second case of injury of the vein, alluded to above, though the plan I have proposed was present to my mind, I was withheld at the time, by motives of delicacy, from obtruding it upon my friend who was operating, as well as from a feeling that it was due to his judgment that he should have time to reflect upon a proposal so novel. There was only one opinion among those present—that the femoral vein was injured; consequently there was only one opinion, that the patient was placed in the most certain danger. With this conviction I thought I should be inexcusable did I not state to my friend, that if the case were my own, I should allow the ligature to remain till a sufficient time had elapsed to admit of a fair chance of the artery being obliterated, and then carefully remove it. In such a time I conceived the inflammation would not have exceeded a salutary extent; and the results of the experiments of Sir A. Cooper, Mr. Travers, and Mr. Roberts, on the temporary ligature, presented a fair chance of the proceeding being attended with success, as far as the aneurism was concerned. The advice was followed. In a fortnight the wound was quite healed, and the patient in perfect health. As it is the intention of my friend to publish his case, I cannot go farther into its details.

It would be difficult, perhaps impossible, to collect from a single instance stronger support for the position I have assumed than this case affords. Mr. Hodgson gives, in his work on Diseases of the Arteries and Veins, an interesting and instructive case, communicated by Mr. Freer, in whose practice it occurred, which seems to bear upon the point. The most violent constitu-

tional disturbance, following the application of a ligature to a varicose vein, ceased immediately on its removal. And though on the tying and instant removal of subsequent ligatures, similar alarming symptoms did not fail to arise, requiring active treatment for their reduction (which was accomplished with a favourable result), no one, I think, can doubt, if the ligatures had been allowed to remain, but that a very different termination would have ensued.

Your obedient servant,
SAMUEL HADWEN.

Lincoln, March 1841.

PTOSIS.

To the Editor of the Medical Gazette.

SIR,

IN Mr. Curling's communication on the cure of ptosis by operation, contained in the MEDICAL GAZETTE of March 25th, 1841, he remarks—"A somewhat similar operation has, I believe, been performed by Mr. Hunt, of Manchester, in a case of traumatic ptosis of one lid, consequent upon a division or laceration of the levator palpebræ muscle; but I am not aware of its having been practised in any case of paralytic ptosis." Since I published the account of the new method of operating for this disease,* which corresponds in principle with that adopted by Mr. Curling, I have not met with any other case in which it appeared desirable to resort to this means of cure. The following extracts will however prove that I then considered the operation applicable to instances of paralytic ptosis. After noticing the failure of the operations formerly adopted, the following observation occurs, to which I beg to direct Mr. Curling's attention. "Nor can the same operation be available in cases of ptosis caused by paralysis, or injury of the levator, when we consider that shortening the eyelid cannot restore to this muscle the power which it has entirely lost."† And again, nearly at the conclusion of the paper, "It may be well to repeat, that this method of performing the operation applies only

* North of England Medical and Surgical Journal, Nov. 1839, p. 164.

† Ibid. p. 165.

to the following causes of ptosis, viz.: those occasioned by loss of power in the levator, whether attributable to actual destruction of a part of the muscles, or to paralysis of the nerve supplying it, caused either by injury or disease."* Dr. Mackenzie, in his standard work on the Diseases of the Eye, remarks, "This method may also be useful when this disease arises from congenital deficiency, or from palsy of the levator."† And he concludes his section on paralytic ptosis by the following observation—"Mr. Hunt's operation may be tried in paralytic cases, when no signs of improvement appear. The epicranium‡ is active, depending on the nervous stimulus of the facial nerve, and the plan of bringing the lid under its influence deserves a trial."§

There is one objection to such an operation in paralytic cases, even although the power of raising the lid were restored by such a proceeding. In most of these instances all the branches of the third pair of nerves are paralyzed, and in consequence of the connection of one of them with the lenticular ganglion, from which body the ciliary nerves supplying the iris proceed, the circular muscular fibres of the iris generally become paralyzed, and a widely dilated pupil is the result. It is a question worthy of consideration, whether continued exposure of the retina to a greater quantity of light than usual, which must be the consequence of such dilatation of the pupil, may not materially interfere with the integrity of the functions of this delicate nervous structure; and thus lay the foundation for amaurosis.

Paralysis of the third pair of nerves may depend upon some altered condition of the vascular system of that part of the brain connected with the origin of this nerve, or with its course through the cranium, unaccompanied by structural disease; or upon some tumor, abscess, or other organic cerebral affection. I am induced to believe the former the more frequent. The difficulty of the diagnosis in the incipient stage is noticed by Dr. Mackenzie. If the paralysis is not confined to the structures supplied by the third pair,

but affects other parts of the face, or if the patient has been subject to fits for a length of time, as in the case reported by Mr. Curling, there is great probability that a slow structural change is going on within the cranium, and the prognosis is decidedly unfavourable as regards the fatal tendency of the disease. In such cases the operation may add much to the patient's comfort during the remainder of his life, if the objection of the exposure of the eye to light, with dilatation of the pupil, should prove groundless. Among the other cases I have not met with a single instance, either in private or hospital practice, which has not yielded to the medical treatment usually recommended, although, in many cases, three or four months elapsed before the entire removal of the disease. I fully agree with Mr. Curling in the propriety of not operating for strabismus in such cases. In the common forms of this affection the patient has the full power of commanding the direction of the affected eye when the sound eye is closed; but, in paralysis of the third pair, affecting only one eye, the closure of the sound eye produces no change in the patient's power of direction of the diseased eye; the cornea being still turned outwards by the abductor.

I am, sir,

Yours respectfully,

R. T. HUNT.

Manchester, March 30th, 1841.

ON DISTORTIONS OF THE CHEST AND SPINE IN CHILDREN FROM ENLARGEMENT OF THE ABDOMEN.

By JOHN SNOW, M.R.C.S.*

(For the London Medical Gazette.)

It is not my intention to describe the various deformities to which the chest and spine of children are liable, but only to speak of one or two distortions which arise from enlargement of the abdomen—a cause of deformity which, hitherto, has not, that I can find, been recognised by authors.

I shall relate only one, out of a few cases that I have witnessed, which will serve sufficiently to illustrate the points that I wish to establish.

* Read at the Westminster Medical Society on March 13, 1841.

* Mackenzie, Practical Treatise on the Diseases of the Eye, 3d edition, p. 167.

† Ibid. p. 181.

‡ Occipito-frontalis muscle.

§ Mackenzie, Practical Treatise on the Diseases of the Eye, 3d edition, p. 184.

Aug. 16, 1839.—Hugh Lynch, a twin child, aged two years and five months, has had a double scrotal hernia from birth. He has been ill for the last four months; his mother says much in his present condition. The abdomen is very large and tympanitic; the chest is broad behind, very narrow in front, and flattened at the sides; the sternum projects forwards very much, especially at the lower end. The cartilages of the ribs, instead of passing outwards from the sternum on each side, leave that bone at an angle by no means very obtuse, and pass backwards to meet the osseous part of the ribs at another angle; and the cartilages of the false ribs project laterally from the bony portion, so that the lower part of the chest is much expanded where it unites with the enlarged abdomen. The last of the dorsal and first of the lumbar vertebræ project backwards, whilst the lower lumbar vertebræ project forwards and the sacrum backwards. The child is emaciated and feverish; its bowels are disordered, and its appetite is craving. Its mother feeds it chiefly on potatoes. The breathing is quick, the inspiration being easy, but the expiration difficult, and attended with an effort approaching to a cough; the upper part of the air-passages being closed after each inspiration, and then the air escaping with a slight sound, similar to that which takes place after the breath has been held for the performance of any muscular exertion. During each inspiration the abdomen descends and protrudes, and the cartilages of the ribs are forced inwards on each side of the sternum. During expiration, on the contrary, the abdomen retreats, and the ribs return to their previous situation. There is loud puerile respiratory murmur, and the chest yields a clear sound on percussion at all parts.

To take some Hydrargyrum cum Creta, and be fed in a more rational manner.

Sept. 27th.—The child is more emaciated. His belly is still large, but much less than before. His chest is of the same form, but the cartilages of the true ribs do not fall in so much during inspiration; those of the false ribs, however, are drawn inwards by the diaphragm at each inspiration, and so project towards the lower end of the sternum, whilst a hollow is left just beneath at the scrobiculus cordis.

The thorax yields a clear sound on percussion, but there is a mucous rale.

The child died on Oct. 29th.

Examination, seven hours after death — The spine is now pretty straight. Abdomen very much less than formerly, but yet tumid. The chest yields a dull sound on percussion throughout the greater part of its extent, although a few hours before death it sounded clear. On opening the abdomen, the diaphragm, instead of its usual arched form, is found to be stretched horizontally across the body, so that it is not so high as the seventh rib. The lungs are healthy in structure, but the whole of the left lung and the lower lobe of the right are collapsed and totally void of air, and gorged with dark fluid blood; the remainder of the right lung is crepitant and healthy. The heart is healthy, but the pericardium contains three or four drachms of serum. Each rib is enlarged into a spongy head at the part where it unites with its cartilage.

The large intestines are distended with flatus, except in portions where they are firmly and preternaturally contracted. The colon is so much lengthened that it crosses the abdomen three or four times. The cæcum is in the usual position, and from this the colon extends to the left side and back again, then passes upwards to the stomach, across the abdomen; and down the left side in the usual route to the sigmoid flexure; which flexure extends into the right iliac fossa, and back to the median line, where it unites with the rectum. The remainder of the abdominal viscera were healthy. The head was not examined.

In order to shew satisfactorily that this deformity of the chest is caused by the enlargement of the abdomen, I must prove that the space within the thorax is increased by any great distension of the abdomen, and not diminished, as is generally supposed. As the belly increases in size, the false ribs, with their cartilages, are pressed upwards, and approaching to a right angle with the spine; the circumference of the chest is thus increased, and the abdominal muscles, which by drawing down the ribs are the chief agents of expiration, can but ill perform their duty; they are kept on the stretch by the bulging out of the viscera, or whatever they enclose. Moreover, the diaphragm,

being attached to the base of the chest all around, has its borders drawn further apart by the increased circumference of the thorax, and thus its natural arched form is removed; it approaches to a plane partition, and the chest, so far from being encroached upon by the abdominal cavity in this direction, has its perpendicular length increased.

I may here state I have always observed that the difficulty of breathing arising from enlarged abdomen, whether in human beings or quadrupeds, consisted in obstructed expiration, and not obstructed inspiration, when there was no other cause of dyspnoea.

The bellies of children are subject to a very much greater proportional enlargement than ever obtains in the adult, and the cartilages and ligaments of the ribs being more flexible and distensible, the expansion of the base of the chest becomes very great; and as the lungs are compelled by the atmospheric pressure to occupy every part of the chest, they must either be preternaturally distended, or the chest must be depressed in some other direction. Now as the ribs and their cartilages are slender and flexible in children, the latter takes place; the chest becomes depressed laterally, and the sternum projected forwards, whilst a channel is left down each side of the chest where the cartilages unite to the bony portion of the ribs. The action of the diaphragm, which presses down the abdomen, and at the same time draws up the cartilages of the lower ribs, during each inspiration, makes room for more air than the lungs are inclined to receive, and the sides of the chest are pressed further in during each inspiration, and return again during expiration: thus the motion of the ribs becomes the reverse of the natural one. I do not conceive this arises from the mechanical resistance of the lungs, but from the sudden stoppage at the throat to the further access of air, which I have observed to be never absent during this deformity with inverted motion of the ribs. It is made evident by the slight explosive sound when the passage is again opened at each expiration. This check to the further ingress of air is no doubt a voluntary or instinctive effort to avoid the uneasy sensation arising from too great distension of the lungs. I do not think it consists in a

closure of the glottis, but in the approximation of the posterior palatine arches, and the pressure of the root of the tongue at the same time against the palate of the mouth: the method by which, as Dzondi has discovered, the breath can be held. It is the office of the serratus magnus and the pectoral muscles to expand the sides of the chest during inspiration, but the diaphragm enlarging the chest more powerfully in another direction, these muscles yield to the atmospheric pressure, and eventually, so far as respiration is concerned, become paralysed.

I have never seen enlargement of the abdomen to great extent in a child under three years of age, that was not accompanied with this deformity of the chest. The degree of deformity is always in proportion to the enlargement; and in observing any individual case, the deformity is found to increase with the increasing size of the abdomen. Even when the enlargement of the belly is not great, there is a tendency to this deformity observable in the slight lateral projection of the cartilages of the false ribs. After the age of three or four years I have not observed this deformity to commence, probably because the ribs become of a strength which prevents it; besides that the abdomen is not so liable to become tumid.

The other deformity, that of the spine, seems to be only an occasional, and not a constant attendant on enlarged abdomen: I think it is in the worst cases that it prevails. It consists in a projecture, frequently an angular one, of the last dorsal, or great lumbar vertebra, or both. In the case I have, just detailed it was accompanied by a secondary projecture of the sacrum; and in another case it was attended with a slight lateral deviation. This projecture of the spine is probably caused by the stretched abdominal muscles and integuments, drawing, by means of the pelvis and chest, on the opposite ends of the spinal column, whilst the increased contents of the abdomen make a resistance in the centre. That this angular projecture of the spine depends on disease of the bodies of the vertebrae in the first instance, we are forbid to suppose, by the fact that the projecture subsides as the abdomen diminishes.

In one child, an angular projecture

for which the formation of issues had been previously recommended, perfectly disappeared as the child resumed his health, under tonic and alterative medicines, with attention to diet, and bandaging of the abdomen. It most likely depends on partial absorption of the intervertebral substance, or bending of the bodies of the vertebræ at the affected part, and, if continued, might no doubt lead to permanent disease.

Baron Dupuytren, in a paper published in the "*Repertoire Général d'Anatomie et de Physiologie*," in 1828, described a deformity of the chest of children, which I believe, in many of his cases at least, to be the one of which I am speaking. It occurred in children badly clothed and fed, born of unhealthy parents, and living in damp situations, and was accompanied, in most cases, by enlarged tonsils, requiring sometimes to be extirpated. He said that there was a keel-like projection of the sternum in front, and a sharp prominence of the spine; that the ribs were not only flattened, but that they were sunk into the chest as if they had been compressed from one side towards the other. This deformity was accompanied with great difficulty of breathing. He did not mention the abdomen, except in his preliminary remarks, to say that there was a projection forwards of the sternum and belly; and he only alluded to it, I think, in one of his illustrative cases, in which, however, he said the belly was five times as large as the chest. In another case he spoke of the width of the chest at the base. He appeared to attribute the deformity to arrest of ossification, and softness of the bones; and recommended some mechanical measures and exercises, in addition to medical treatment, for its cure. He spoke of some cases in new-born infants, which, I think, could not have the same origin as the cases I have seen. The nature of the connection between these deformities and the enlargement of the tonsils, he could not tell.

I have only seen one case since I read Baron Dupuytren's paper, and in this there was no enlargement of the tonsils. I can, however, suppose that the obstruction to inspiration from enlarged tonsils, might cause the ribs of a child to be pressed inwards by the

atmosphere, and produce a deformity of this kind.

In the *MEDICAL GAZETTE* of January 12th, 1839, is a letter by Mr. Rees, describing the deformity of the chest of which we are treating as occurring in four or five children seen by him at the Tower Hamlets Dispensary. He describes the depression at the line of union between the ribs and their cartilages, producing a channelled appearance external to the sternum on each side; and he likewise describes the inverted action of the ribs in respiration. Mr. Rees does not mention the abdomen, except in the case he relates for illustration, in which he incidentally says it was tumid. He attributed the deformity to chronic pneumonia, which causing the lungs to shrink and become solidified; the ribs are forced in by the atmospheric pressure to occupy the space. We can perceive that shrinking of the lungs might have this effect, but in the cases I have witnessed there was no disease of consequence in the lungs, except in one child that had hooping-cough.

Mr. Amesbury describes this deformity, and the enlargement of the abdomen in connection with it; but he does not speak of them in the relation of cause and effect. He attributes this deformity to weakness of the muscles. He says, "Deformity of the chest, arising from weakness of the muscles, commonly takes place during teething, but may be produced by any complaint that tends to debilitate the system. This distortion usually assumes the form called 'chicken-breast.' In this variety of deformity the chest is usually more or less contracted laterally, the sternum is thrust forward, and the abdomen is preternaturally enlarged. The intercostal muscles act very little in respiration, the breathing being principally abdominal." Together with medical treatment for the improvement of the general health, Mr. Amesbury recommends bandaging the abdomen for the cure of this deformity.

Baron Dupuytren and Mr. Amesbury do not mention the reversed action of the ribs in breathing. Mr. Rees and Mr. Amesbury do not allude to any deformity of the spine; and the projection to which Baron Dupuytren alludes appears to be one of the whole spine, and not of particular vertebræ.

In two or three of the cases I have seen, the inferior extremities became deformed under the weight of the enlarged belly, but it was the joints which yielded, and not the shafts of the bones; and there was only in one case the enlargement of the heads of the bones peculiar to rickets: where rickets exists it may assist to aggravate the deformity, but cannot of itself cause it. A scrofulous diathesis, by predisposing to mesenteric disease, may be considered favourable to the development of these deformities; but in the cases I have seen, I do not remember to have observed enlarged glands, or other decided marks of scrofula. And in the only two cases in which I have had the opportunity of an examination after death, there was no disease of the mesenteric glands, and the enlargement depended chiefly on the elongation and distension of the colon.

I have generally been able to trace the increased size of the belly to improper food, and have found it mostly amongst those infants who, from the poverty or intemperance of their parents, are, after weaning, fed almost entirely on potatoes. I believe the best treatment to consist in alteratives and tonics, with occasional purges, and the careful avoidance of crude and indigestible food. At the same time the abdomen should be firmly bandaged, as recommended by Mr. Amesbury, which measure, whilst it assists to reduce the belly to its natural size, will relieve the breathing by aiding the efforts of expiration; and by pressing the diaphragm upwards, will reduce the capacity of the base of the chest, and thus lessen the cause of the contraction higher up. If this deformity be left to itself, and should not prove fatal, the serratus magnus, and other muscles, may not recover their power of expanding the ribs, or the ribs may have become firm in their abnormal shape, and the deformity may continue, after the enlargement of the abdomen, which gave rise to it, has subsided. I have seen two or three cases of this deformity in grown-up persons, which, so far as I could gather the history, appear to have originated in this manner.

Thus, then. I have endeavoured to establish that enlargement of the abdomen in children leads to deformity of the chest, and occasionally of the

spine; and that although the deformity of the chest, or one nearly resembling it, may now and then arise from other causes, yet that this enlargement is of itself sufficient, and will never fail to induce it, if proceeding to any great extent in young children.

CURE OF STAMMERING.

To the Editor of the Medical Gazette.

SIR,

On the evening of Monday, the 8th instant, I transmitted to you a communication on the cure of stammering, but it appears to have been too late for your number of yesterday, which, however, contains two interesting letters on the same subject. These papers are valuable to me, as conveying statements which can be relied upon regarding the mode of practice and views of Professor Dieffenbach and Mr. Yearsley, both of whom stand high in professional estimation. They also settle the question of priority in the performance of the operation, which I was anxious to know. It appears Mr. Yearsley's first operation was in December last, and that of Dieffenbach on the 7th of Jan., 1841, while my first operation for stuttering was performed in September last, being about three months prior to theirs. As noted in my letter of the 8th instant, it is a curious circumstance that we should have been prosecuting the same subject about the same time, and with somewhat similar views, without the knowledge of what each other was doing.

Mr. Yearsley's notion as to the cause of stammering, and the mode of cure, are very nearly the same as my own; but not entirely so; and after an attentive perusal of his paper, I see nothing in it which can lead me to alter my opinion, as stated in my letter of the 8th, namely, that stuttering is caused by the glottis being prevented from rising sufficiently to admit the quantity of air required, and acting with that promptitude necessary to secure free and correct enunciation. Mr. Yearsley, on the contrary, conceives that *no* air is allowed to escape from the chest; and that there is besides an impossibility of any passing forward into the mouth, from the absolute closure of the anterior fauces by approximation of the

dorsum of the tongue and palate. I think it will be found that there is always a certain quantity of air admitted into the mouth of the greatest stammerer, although not enough to enable him to speak correctly and freely; and that the pressure of the lips causes this air to react on the epiglottis and root of the tongue, so as to cause a still farther closure of the larynx and difficulty of egress of air. In proof of this I may observe that stammering is most apt to happen when the labial or palatine consonants occur; the former from the action of the air just stated, the latter by the pressure of the tongue against the palate, tending to produce the same effect. The fact of stutters being able to sing what they cannot speak, seems to favour the same view; and both Dieffenbach's, Mr. Yearsley's, and my own mode of operating, tend to secure the same freedom of opening of the glottis; the former by drawing the root of the tongue, and of course the epiglottis, upward and forward; the latter by removing the obstacle to its free opening, in allowing it to rise by removal of the enlarged tonsils, and its advancing forwards by removing the bridling of the tongue by division of the frænum, or preventing the titillation of the enlarged uvula, stimulating that ever watchful sentinel, the epiglottis, to too vigorous exercise of its functions of guarding the entrance of the glottis from all impertinent intruders.

As to the mode of operation, that of Dieffenbach is evidently and avowedly a formidable one. Mr. Yearsley's and my own are comparatively simple. For the division of the frænum linguæ I use a pair of sharp-pointed knife-edged scissors; and although I have had occasion to cut so freely as completely to expose the blood-vessels in that situation, I have never had more than a tea-spoonful or two of blood from any single operation. For the excision of the tonsils I observe Mr. Yearsley uses a tenaculum and scalpel; but I have no hesitation in saying that the instrument I use for the purpose is one which will effect the operation with much greater exactness, celerity, and safety. I regret that I cannot name, at this moment, the inventor of this ingenious instrument; as I would wish to award the full mead of praise to every man who makes an improvement in any

department of our profession. It was invented about two years ago, I think, by a London practitioner, for excising the tonsils, and consists of an oval ring, with an oval concealed blade, attached to a handle, with finger-bowls to hold it with the more steadiness. The flat edge is pressed along the tongue, and is then turned and pressed laterally, so as to cause the enlarged tonsil to protrude through the ring, when it is to be secured in that situation by pressing onward a sliding skewer attached to the handle of the instrument, when the handle of the cutting blade is pulled forward, and of course cuts off that portion of the tonsil which has protruded beyond it. The pillars of the palate are effectually protected from injury by the sheath in which the blade is placed, and there is no risk of injuring the internal carotid by any struggling of the patient, which might occur in the other mode of operating with the tenaculum and scalpel bistoury, especially in young patients. If the tonsils are very little enlarged, but still so much so as to require excision, from their relaxed state, and might not protrude through the ring so as to be readily secured by the skewer referred to, it might be assisted by a tenaculum, to extend it whilst cut by the blade, as in other cases. The instrument I prefer for amputating the uvula is a pair of scissors rounded at the point, so that they cannot possibly injure the posterior fauces, and a pair of forceps, such as those used for the extraction of polypus, which at once serve the double purpose of commanding the tongue and uvula during the division of the latter by the scissors.

I can bear testimony to the correctness of Mr. Yearsley's statement of the improvement of the voice which occurs immediately after the excision of the enlarged tonsils of those who are not stammerers, but articulate badly from enlargement of these organs. Where it has been husky and guttural in a high degree, the change is so great and immediate, that it could scarcely be credited by those who had not heard it; but I have so often performed those operations, that I consider it may be regarded as a certainty, if properly performed, and the cases have been judiciously selected. In my former letter, when stating the remedies I had found useful, where stammering, hawking, and

coughing, were occasioned by a relaxed state of the fauces, and which, of course, are always associated with an irritable condition of the mucous membrane, I omitted to name the nitrate of silver, either in substance or solution, as one of the most important remedies.

I am, sir,

Your obedient servant,

JAMES BRAID.

10, Piccadilly, Manchester,
March 13th, 1841.

CASE OF
POISONING WITH GUN-BARREL
"BROWNING."

To the Editor of the Medical Gazette.

SIR,

A FEW months since, as I was walking through the streets of this town, in company with Mr. Atkinson, surgeon to the Union, a respectable tradesman of the name of Beckley rushed up to us with a death-like countenance, in a state of the utmost trepidation, exclaiming that his "son was poisoned." We immediately proceeded to his residence, and found a child, about five years old, sitting upon its mother's knee, making ineffectual attempts to vomit. He complained of a constant burning pain at the epigastrium, a peculiar sensation in the throat, and the pulse was feeble and quick. He looked listless and heavy, but was perfectly rational, replied promptly to questions, and was extremely obedient in adopting the measures of relief which we recommended.

It appeared that his father, who is a gunsmith, had left a bottle containing "browning" within reach, and, during his temporary absence, the child had swallowed a considerable quantity of its contents. Gun-barrel browning is composed of bichloride of mercury, sulphate of copper, and the tincture of the sesquichloride of iron; a precipitate is the result of the union of these heterogeneous ingredients.

The first object was to neutralize the bichloride of mercury, if any existed in a free and uncombined state; to effect which, copious draughts of milk, combined with whites of eggs, were administered. The successive doses, owing probably to the emetic action of the sulphate of copper, were ejected after

short intervals, in a partially coagulated state. The poison having at length ceased to act upon the stomach, or the organ having become insensible to its action, a slight ipecacuan emetic was given, followed by draughts of milk: vomiting was renewed, the pulse became more natural, a gentle perspiration broke out, and the child was taken to bed, where he soon fell asleep, and awoke convalescent.

REMARKS.—The quantity of corrosive sublimate swallowed could not have been very considerable, as a pint of the mixture contained only about a scruple of the salt, with the same weight of the sulphate of copper. All authors, however, agree in assigning dangerous properties even to a minute dose. Orfila, Campbell, and Smith, state that three, four, or five grains, will cause death in the course of the second, third, fourth, or fifth day. Irritation of the alimentary canal, the first symptoms of poisoning, had been clearly induced, and was as manifestly allayed, almost instantly, by the antidote. Professor Orfila has related many satisfactory experiments in proof of the virtues of albumen in destroying the corrosive properties of bichloride of mercury, and converting it into the comparatively harmless albuminous protochloride. Peschier considers that the white of one egg is sufficient to render four grains of the poison innocuous. Dr. Christison also remarks, that the prompt exhibition of albumen, just as the symptoms of uneasiness appear, prevents further ill consequences.

With regard to the salts of copper, Orfila found that albumen is also the surest antidote to their poisonous qualities, and his experiments have induced him to recommend that substance in preference to any other. He found that when 25 or 36 grains of verdigris were mixed with the whites of six eggs, the poison which, if pure, and administered alone, would have caused death in three hours, did not produce it for seven days; and had no effect whatever for five days, although in some experiments the œsophagus was tied, to prevent its expulsion.

I have the honour to be, sir,

Your obedient servant,

R. H. ALLNATT, M.D.

Wallingford, March 30, 1841.

PERFORATION OF STOMACH.

To the Editor of the Medical Gazette.

SIR,

I SHOULD have been glad that a communication from my pen, likely to be the last, had been of some utility in relation to the cure of disease, rather than the record of an unusual and distressing case. It may, however, be of some service to have put down accurately the symptoms which attended such a case, and will probably designate all similar ones, in order that none concerned may be taken by surprise, encouraged by false hopes, or led to adopt what is called active treatment, which can but accelerate the fatal event.

Cases of perforation of the stomach or intestine are already on record. I have quoted, as I recollect, in my lectures, as many as ten or twelve; but it has not fallen to every one's lot to have seen, as I have, or been intimately acquainted with two. I have no means here of consulting a single book on the subject, nor indeed would it be to much purpose. The general fact is, I think, that the accident takes place always without warning; never by laceration, but by the giving way of a small insulated ulcer, which is found probably with callous edges, and of so small a size that a common drawing pencil would just, as in the present case, pass through it. Of course I have not to learn that perforations of the intestine occasionally happen in fever and other acute diseases; but these cases of perforation of the stomach are of a totally different character, and their awful peculiarity is, that they happen in the midst of health.

I cannot say how many years ago it is, but it chanced that at the very time when I was lecturing on the various maladies of the stomach—for which a text is supplied by those two unfortunate titles, gastritis and dyspepia—a letter was put into my hands from my son, the late lamented Dr. John Badham, relating the fate of a young lady with whom he was intimate, who had parted with him and others one evening after a ball in florid health, and was almost immediately attacked with atrocious pain in the belly (which was, of course, mistaken as to its nature), and went on without a moment's palliation till she died, which happened in

about twenty-four hours. On examination it was found that a small ulcer, evidently of some standing, had been developed from within, and proceeding from the mucous coat to the peritoneal, had at length given way. It was this distressing case that led me immediately to consult authorities which were then at my hand, while the case itself made an indelible impression.

Dr. Cox, a gentleman who is settled at Naples, requested me, a few days since, to see with him a case of alarming character. He had been summoned at ten the night before to a young woman in dreadful suffering from abdominal pain, with which she had been seized at four in the afternoon (at three she was still in perfect health). After careful examination he had no hesitation in considering the case as enteritis. Accordingly she was largely bled, but with very small relief; and as things continued in the same state, a few hours later this practice was repeated, and thirty-six leeches, with fomentations, &c. &c. were also applied.

I went with Dr. Cox about eighteen hours after the attack; and the following were my notes:—

The pain had begun under the false ribs of the left side, quite suddenly, but soon became abdominal. She lies with her knees up, and cannot turn ever so slightly without great aggravation of pain. Pressure cannot be endured for a moment, but still there is no great tension or tympanitic resistance—no probability of the existence either of air, or fluid effusion.

She has great and incessant thirst; but, notwithstanding all she drinks, no action of the kidneys: she has passed urine but once, and in small quantity, since the seizure.

The bowels had acted but the day before, and therefore could not be considered as obstructed.

The tongue has no remarkable character, neither of redness nor coating of any kind; there is a light brown speck down the middle, and to the finger it is dry, but not remarkably so.

The pulse is exceedingly small, rapid, and difficult to be felt.

There neither is, nor has been, any sickness or vomiting; and even nauseous medicines have been retained.

The blood has no appearance of a buffy coat.

Her intelligence was perfect; she was, she said, a stranger to illness of any kind: had but lately arrived in Naples, had taken no cold, but for a short time had cared rather less for food.

I saw her again a few hours later, when her sufferings were intolerable, and before next morning, thirty-eight hours from the attack, she expired.

The remaining report is from Dr. Cox. "Intestines acutely inflamed. Ulceration opening near the cardiac extremity of the stomach, and on its greater curvature; its edges smooth and indurated, and evidently but of recent formation. (Had often made mention of pain or uneasiness on her left side.)"

The rest is of small importance. In conversation with Dr. Cox I had ventured on the whole so far to differ from him, as to be inclined to consider the disease rather as of the investing membrane than of the bowel. I had often seen peritonitis assume a very ambiguous character, but it was not till after the death of the unfortunate patient that the case mentioned above occurred forcibly to my memory; and accordingly I addressed a note to Dr. Cox, stating this case, and adding, that as, either on his supposition or mine, death could not well have occurred so soon, it was really important to ascertain the state of the parts.

The weather at Naples has been, and that for the whole winter, so bad, that a patient could scarcely be worse circumstanced: a fine day has only been occasional. Those who have been sent to Nice must not expect any thing better in the climates of any parts of Italy.—I remain, sir.

Your obedient servant,

CHARLES BADHAM.

Naples, March 7th, 1841.

MEDICAL GAZETTE.

Friday, April 9, 1841.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas nolo veniendi in
publicum sit, dicendi pericula non recuso."
CICERO.

SIR CHARLES BELL ON MEDICAL REFORM.

In times of civil contention, said the ancients, it behoves every citizen to

take his side, and not affect a neutrality dangerous to the state; and now that our medical republic is so sorely distracted by fears and jealousies, we hail with pleasure each document which gives the deliberate opinion of some man of note.

Sir C. Bell, whose pamphlet is now lying before us*, comments on the two bills which have attempted to apply a salve to our professional grievances; and, like all other persons, he condemns them. When we *do* agree, as Sheridan says of stage concord, our unanimity is wonderful; and the bills for improving the medical profession have reconciled the most violent antagonists, and, like some great public calamity, have made all other misfortunes appear trifling by comparison.

Sir C. Bell, however, though utterly rejecting the little medical parliaments, and all the other queer devices proposed to make us happy, is by no means perfectly satisfied with things as they are. He is a reformer, but then it is after his own fashion; he does not come into the field with any well-known uniform on his back, but fights like a partisan, in plain clothes, and does not draw up with the regular troops.

The consequence of this is, that he cuts right and left without much mercy; old corporations and new reformers share his censure, and his motto seems to be

Tros Tyriusve fuat, nullo discrimine agetur.

Sir Charles warns the members to whom his pamphlet is addressed against the bias arising from local prejudices; and so far he does well; but when he begs them to reflect that in London they are "exposed to the influence of men who form their judgment on very limited experience," and "who have

* "A Letter to the Members of Parliament for the City of Edinburgh, on the two bills now before Parliament for the Improvement of the Medical Profession. By Sir Charles Bell. 1841."

not hitherto taken an enlarged view of this matter," we think that, in phrenological language, his organ of caution is too strongly developed. The members for Edinburgh, like all other M.P.s, have in London the opportunity of learning the wishes of medical men of every calibre; from the dashing practitioner who clears his 3 or £4,000 a year, down to him whose scanty revenues are not to be mentioned to ears polite—every shade of opinion is daily unfolded to our legislators. These varied sentiments cannot be attributed to local prejudice; they are not the unmixed growth of the London district, nor alien to the feelings of men born in Hants or Salop, but the calm representation of English opinion elaborated by long discussion and experience, and expressed in a kind of national congress. Far from London being under the influence of local prejudices, it seems rather to approach the undefined line where impartiality borders on indifference; so that metropolitan sluggishness occasionally forms a curious contrast with provincial vivacity. In fact, London, instead of being the heart of the empire, as it is often called, has sometimes seemed to us more analogous to the brain—the source of sensation to every other part, but itself almost destitute of feeling.

Did we find, for instance, that Mr. Warburton's Bill, that bundle of whims and oddities, was discussed in the capital with heat and agitation, as a thing likely to annoy the profession extremely? or, was it talked of, like the fortifications of Paris, as a strange freak that nobody need mind? Does Mr. Hawes's bill, again, fill us all with perplexity and terror? We can assure Sir Charles that every one waits for its extinction with the most philosophic composure, and that scarcely an epigram will be written on the occasion.

Sir Charles tells the story of Walter

Scott finding Mungo Park throwing stones into the pools of the Yarrow, that he might learn to judge of the depth of the rivers in Africa by the time the bubbles took to rise from the bottom. Park was at this time a country surgeon, with a practice of £150 a year, and "rather than suffer the privations of his condition, he was contemplating a perilous adventure." Mungo Park's talents clearly did not lie in the country practice line; "to sit by the side of a groaning woman till dawn," as Sir Charles phrases it, was not his *forte*, and he did well to give up the Yarrow for the Niger. This anecdote scarcely proves, as it is intended to do, that the income of country surgeons is so small that the legislature must, at all events, refrain from increasing the expense of their education. The case is clearly an exception; and we have no doubt that Mungo Park's successors have made larger incomes on the same ground: but *non omnia possumus omnes*; and the man who was destined to immortality as a traveller, was unable to grow popular amongst the farmers' wives on the Yarrow.

Nevertheless, we agree with Sir Charles Bell, that some of the studies which adorn the Corinthian capitals of the profession may safely be dispensed with in the case of ordinary practitioners, in spite of the crotchets of the one-faculty men.

How are these things managed in other countries? Why, they found professorships, and teach medicine gratuitously, or very cheaply, lest the poorer parts of the kingdom should lack advice. But would any one make our students "paupers depending upon the state?" No one, we should hope; neither the author of the letter, nor we, at any rate.

But our agreement with him in this point makes us differ from him when he laments the sums levied on the "poor students" in the University of

Edinburgh; for the prodigious superfluity of M.D.s yearly sent forth by this body is almost a demonstration that the fees by no means amount to what merchants call a prohibitory duty. Sir Charles says, that in his office of Dean, he has of late years "exacted from their pockets eleven hundred guineas annually," which go to government. The newspapers often tell us the number of oxen and sheep consumed every year in London; and the tale appears immense till we recollect that when divided among a million eaters, the quotient, or ration of beef and mutton for each mouth, is not very large: just so, if the eleven hundred guineas are extracted from five or six hundred purses, the tax on each will not be heavy. At the same time he is perfectly right in disapproving of the number of different lecturers whom the student is obliged to hear, and of the protraction of minor subjects through six long months. Far better would it be to go over the more important topics a second time, and spend more hours in clinical instruction, and in attending cases under skilful superintendence. This would be a great improvement, but would be far from satisfying every one: for a social problem remains to be solved, compared to which the riddle of the Sphinx was a joke. It is this: to devise a distinction so easy, that every capacity may earn it; so cheap, that every fortune may buy it; so quickly won, that the slenderest patience may wait for it; yet so brilliant, that, like the coat of a clergyman or an officer, it may be a universal passport in society.

The legislature, complains Sir Charles, when they wanted to pass a Medical Act, sent the inquiry to a Committee, "and then there is a farce of taking evidence and receiving the statements of corporate bodies, all tainted with the imperfections of a rude age."

But surely the Professor would not have rejected all evidence save that of the malcontents; and after the Committee had heard the statements of frail contented creatures, they must have hastened with a higher zest to evidence untainted by imperfection; for none was excluded—good was allowed admission as well as bad. Perhaps the following sentence contains a nearer approach to the marrow of the question:—"The radical defect being the attempt to legislate for a profession, to reconcile the interests of medical men, instead of looking steadily to the interests of society."

In rude ages, or even now in some continental countries, it may be advisable for the supreme power in the state to meddle with the details of ordinary life. Catharine of Russia issued regulations for the conduct of evening parties; but though it might be easy to prove to the satisfaction of a Committee that for want of a ukase, ices melt, and lemonade grows lukewarm, no one has yet advised us to copy the Muscovite model.

In Malta, again, our government has fixed a tariff for medical and surgical advice, and while venesection is recompensed by six taris, or 10½d., the reduction of hernia claims six times as much*.

In this country, however, we leave the settling of the tariff to doctor and patient, with probably less dissatisfaction in the main, than on the straight-laced system intended to prevent all disputes.

Some few and obvious improvements might be safely attempted. First, sweep away the minor examining bodies. Secondly, let each remaining board qualify the successful candidate for practice throughout the British empire. Thirdly, on all occasions where the state comes in contact with

* Hennen's Medical Topography of the Mediterranean, p. 544.

our profession, let a more liberal scale of remuneration be adopted: it is degrading to the profession, and therefore injurious to the public, that the services of an assistant-surgeon in the army, or of the medical officer of a Union, should be rated at less than those of a tolerable clerk in a house of business. These are points with which the State may advantageously interfere. But we would warn legislators and reformers that the customs of a nation cannot be suddenly changed by Act of Parliament. The very attempt is painful. The fable of the shrubs which, when pulled up, dropped blood, and uttered lamentable cries*, is but a type of the uneasiness which such attacks occasion. Old habits are found to possess life as unexpectedly as the myrtle-trees in Virgil, and to part from it almost as reluctantly.

A very delicate point touched upon by Sir Charles is the indifference of the College of Surgeons to the moral influence of the profession. He complains of their receiving certificates from anatomists of irregular habits, and observes that during his thirty years' experience of teaching in London, hundreds of young men entered the profession with the worst examples before them. But what would have been said of the College, had it attempted an inquisition into the morals of lecturers, or refused a certificate from a teacher, because, though a good anatomist, he was a free liver? The only solution that we can propose for this dilemma is the establishment of medical colleges, as we set forth in our last number, where each professor would be in some measure a sponsor for the character of the others. As it is, there is no doubt that even the study of the human frame (which Galen called a hymn to the Deity,) may tend to blunt the finer feelings of our nature†.

One more point, and we must have done—at least for the present. Sir Charles Bell complains of the small rewards bestowed on the exertions of practitioners of physic, compared with those lavished on other learned professions. So far he is right: no medical practitioner occupies in English society the station of a bishop or a judge. But when he goes on to say that there is no worthy tribunal to judge the merits of our profession, and that all success depends on ignorant rumour, or the prejudice of fashion, we are compelled to differ from him. Indeed, we may quote his own example against his own theory. In any scientific association, from the Neva to the Tagus, when the nerves become the subject of discussion, the name of Bell is quoted as an authority. Is not this fame? Can the most brilliant leader on the northern circuit, or the deepest equity judge, go higher? Our utmost exertions, says Sir Charles, can gain no more than the gratitude of a person subdued by sickness, whose opinion is farther questioned by old ladies round the tea-table. Here, again, we think the Edinburgh professor too hypochondriac, and would defy all the ancient dames in the kingdom, inspired by the strongest Howqua, to wither one leaf of his laurels.

We could have wished for something less dis-jointed and more detailed than this letter, from a man of genius like Sir Charles Bell; yet, such as it is, it will be perused with advantage, and will supply its readers with larger materials for thinking than many more regular disquisitions.

per feeling, extinguishing religious, as well as natural sentiment, there are none like a dissecting-room. Nothing more necessary, more profoundly useful than dissecting; and no place so productive of evil to youth, when uncontrolled by the presence of a respectable teacher and head, as a dissecting-room."—Sir C. Bell. "A Letter," &c. p. 13—14.

PARIS SURGICAL PRACTICE.

No. II.

To the Editor of the Medical Gazette.

SIR,

FRACTURES of the inferior extremity, when not treated by the *appareil am-donné* in the Paris hospitals, are still for the most part put up with the limb in the straight position, and resting on its back, in a sort of junk formed of a piece of cloth and two wooden splints, not more than two and a half or three inches wide; bags, or cushions of chaff, of an equal length with the splints, being interposed between them and the soft parts. A third splint and cushion is placed on the anterior part, and the whole tied together, the foot being frequently without proper support. This apparatus is not suited to cases in which inflammation or much swelling exists, as it keeps the part hot, and prevents the application of cold water irrigations, which are now frequently employed in Paris. Neither is it well adapted to compound fractures, as tending to favour suppuration. When a wound exists, it is generally dressed with charpie, and the perforated linen rag smeared with ointment; or, if extensive, and suppurating freely, with poultices. During the dressing, or the reapplication of the apparatus (which frequently becomes loosened), sufficient attention is not paid by the dressers or assistants to support the limb; only one hand, perhaps, being applied to the knee, and none to the lower part. But little general treatment is adopted, except bleeding if there should be much accompanying fever. In fractures of the thigh a long narrow splint extends the whole length of the limb, from the hip to the foot. A second splint on the inside also extends to the foot; and a third short one is placed on the anterior part of the thigh, without any means being adopted for keeping up due extension; and as the apparatus is frequently slack, I should think that shortening of the limb is a very common occurrence, having myself seen some instances of this. Fractures of the upper part of the bone, about the trochanter, or of the neck, are generally treated by Boyer's, or some other apparatus, by

which efficient extension may be made. When the last kind of fracture occurs in old people, the plan of Sir A. Cooper is frequently acted upon, viz. of not applying any apparatus, but merely of keeping the patient in bed for ten days or a fortnight.

Amputations of the leg are frequently performed very low down, in order to enable the patient to wear an artificial foot. This succeeded very well in two boys on whom M. Velpeau operated during my recent visit; and in one of them, when the patient walked, many persons could not tell, without great attention, on which leg the operation had been performed.

An amputation of the leg was performed in February, by M. Roux, on a man 65 years of age, of good general health, but labouring under depression of spirits, affected with gangrenæ senilis. The foot and toes were cold, and completely discoloured, and a distinct line of demarcation existed on the leg, about five inches from the ankle. The patient, however, did not survive the operation more than five or six days.

The question of the propriety of amputation in cases of mortification of the extremities has frequently been agitated; and it is now pretty generally admitted among the profession, that as far as concerns gangrene resulting from wounds or external causes, amputation is frequently advisable; but the great majority (and I may say almost all in this country) are averse from recommending it in the idiopathic kind, though patients have subsequently recovered; and of those who have succumbed, a large proportion would in all probability have died if the parts had been left to separate by the effects of nature. It may therefore fairly be questioned, whether, when there are no other counter-indicating circumstances, the operation might not in some cases be preferable to the chances of recovery afforded by the patient waiting, during months of suffering and confinement, and breathing an atmosphere tainted by the presence of a loathsome disease, for the tedious process of separation of the dead parts from the living.

An operation was likewise performed by M. Roux, about the same time as the preceding one, for the removal of a cancerous tumor, near the size of a pullet's egg, occupying the

left side of the base of the tongue. As its extirpation by the mouth was impracticable, M. Roux performed an operation similar to the one which was successful in the hands of Professor Regnoli, of Pisa, two or three years ago, which consisted in drawing the tongue out of the mouth beneath the lower jaw, through a wound of the soft parts, formed by a longitudinal incision extending from the symphysis to the os hyoides, and two lateral incisions along the edge of the jaw-bone. M. Roux, however, considering that there would be less likelihood of the collection of blood and matter if the lips of the wound were in a more depending position, made his incision through the skin, cellular texture, and platysma myoides, commencing anterior to the facial artery, where it crosses the bone on the left side, carrying it in a semicircular form down to the os hyoides to terminate at the corresponding point on the right side. The muscles were then divided by a sharp-pointed bistoury, being passed into the mouth from below, and the flap being held aside, the tongue was seized with the *pincers de Museaux*, and drawn through the aperture, by which the whole of the tumor was exposed, and excised with comparative facility; though the operator was obliged two or three times to wait a minute or two, on account of the difficulty of breathing, and tendency to syncope, experienced by the patient. The remainder of the tongue having been replaced in the mouth, the edges of the wound were united by suture and adhesive plaster, and the patient was conveyed to bed. He did not, however, survive more than three days. The quantity of blood lost was not very great, and was chiefly from the branches of the lingual artery.

In any similar case, would not the section of the soft parts, from the angle of the mouth to the ascending ramus of the jaw, be a preferable operation, and one attended with less danger than that above described?

Your obedient servant,

EDWIN LEE.

SUDDEN DEATH.

To the Editor of the Medical Gazette.

SIR,

It affords me much pleasure in having it in my power to answer the query of your correspondent, "Inquisitor," contained in your last number, "as to what is to be done in a case of sudden death." Without entering upon a consideration of the various causes producing sudden death, we may, I think, divide the states in which we generally find the individual into two, according to the symptoms presented. In the one we have the quick, strong, resisting pulse, noisy respiration, *warm extremities*, frequently general perspiration, flushed countenance, with some spasmodic muscular action: in this case bleeding is evidently strongly called for. In the other case, on the contrary, as stated by "Inquisitor," with *cold extremities*, cold clammy moisture on the surface, slow and laboured respiration, with feeble, or total absence of radial pulsation, and the other symptoms of depressed vital action (though far from always indicating a ruptured vessel.) In such a case, indeed, it is both "unscientific and malpraxis," and I may add unjustifiable, to bleed the patient. Most assuredly is it "*infra dignitatem*" for any member of so liberal and enlightened a profession as the medical, for one moment to think of so pandering to the ignorance of the crowd collected, or of the jury at the inquest, as to detract blood; and acting not only against knowledge and conscience, but also preventing, by so doing, the only chance of recovery.

In such a case I would briefly but clearly explain my views to those around. I would assure them that to bleed would be certain death. I would recommend the immediate exhibition of diffusible stimuli, and application of warmth to the extremities; and if still urged by the by-standers to bleed, I would positively refuse, and leave the case open, if wished, to a second opinion.

In the event of being quite extinct, I shall only add, that the performance or non-performance of the operation being of no moment, venesection, in order to satisfy the public that "all has been done," may be considered both justifiable and sometimes prudent; but even in this instance I should also apply warmth to the extremities, and give a stimulant; not for the sake of public approval, but to leave no stone unturned, with a view to saving the life of a fellow-creature.

If the above remarks, sir, do not occupy too much space in your valuable periodical, you will greatly oblige me by inserting them in your next number.—I am, sir,

Your obedient servant,

RESPONSOR.

March 10, 1841.

MEDICAL REFORM.

To the Editor of the Medical Gazette.

SIR,

ALTHOUGH you have hitherto shown but little disposition to assist medical reformers, I have sufficient confidence in your impartiality to believe that you will admit the letter of one of these *rare aves* into your columns; and, acting under this impression, I will briefly reply to some of the remarks of a "Provincial Physician," inserted in your last number.

This gentleman very liberally insinuates, that reformers, or those who advocate uniformity of education, title, &c. "are careless of the honour of the profession to which they belong, and heedless of the ultimate effect upon society at large," and that "they only seek their own aggrandizement." These accusations, to the generality of your readers, must appear so absurd, that it may seem almost useless to reply to them; but as others (I am sure without reflection) may entertain the same opinion as your correspondent, I will briefly state what I believe to be the motives which really actuate all true reformers. They contend, that the generality of medical practitioners are insufficiently educated. They also believe that no examination can be efficient without combining medicine and surgery. They are advocates for a good preliminary education. They see the profession, as at present constituted, a perfect chaos—a *rudis indigestaque moles*; or, as Dr. J. Johnson very aptly expressed it, "a body with three heads, all pulling in different directions." They witness the physician obtaining his degree from a dozen different sources; many of them of so disreputable a nature, that the well-educated M.D. is becoming ashamed of the title. They see many who practise as pur surgeons lamentably ignorant of the study of medicine. They find amongst general practitioners many who have passed no examination; some only members of the Hall, and others of the College; yet all possessing nearly the same privileges. Seeing these things, and believing that equality of education would add much to the dignity and honour of the profession, as well as to the respectability of its members, they press on for reform; not afraid, like the "Provincial Physician," to admit young men to the same or to superior privileges to themselves—disregarding all pecuniary considerations—not desirous of self-aggrandizement—but anxious only for the good of the noble science which they cultivate, and for the welfare of the community at large.

The above by some will be considered an overdrawn picture, but let it be observed I

have spoken only of *true* reformers. Many there are whose motives may be questioned; but this cannot apply to the great bulk of the profession, which is now agitating from one end of the country to the other.

So much for the motives of the generality of reformers; and now for some of the "Physician's" objections to our plans: and, first, to that of equality. He asks, "If all are to be captains, who is to pull the boat?" Why, sir, all could not be captains long; one would soon be selected by the rest, from his superior acquirements, to take the command. So with the members of our profession; and I cannot better illustrate my argument than by using your correspondent's own words, viz. "that merit combined with talent, like oil, always rises to the surface;" provided, I would add, that it has a fair field. We must always have men who, in consequence of their superior talents and experience, will be consulted by their brethren in cases of doubt and difficulty. Indeed, I cannot perceive that the proposed changes will in any respect affect the existing grades; for although all will take the same degree, yet it is evident that the great majority will act as general practitioners; and it is fair to presume that those gentlemen who devote themselves exclusively to medicine or surgery will, as at present, be the referee men. Take the College of Surgeons as an example: all undergo the same examination, but how few act as consulting surgeons. The Physician fears that "if all be educated alike, the lower orders will not be attended to, and that the chemist and druggist will take the place of the general practitioner." I have no apprehension of such a result. Well-educated men will always be found to attend to the poor; and the restrictions proposed to be put upon chemists and druggists will entirely, I think, obviate the latter tendency. I could say much about the corporations, as well as the general misgovernment of the profession; but I am anxious only on this occasion to shew that your correspondent's views respecting medical reformers are illiberal and unjust.—I am, sir,

Your obedient servant,

A REFORMER.

April 6, 1841.

To the Editor of the Medical Gazette.

SIR,

IN reflecting upon the present much agitated question of medical reform, and the plans proposed by the advocates for one faculty, and their opponents, I find something of good in each, mingled with much that is to be deprecated. In legislation, generally, the greatest good for the greatest number should be the ruling maxim. The proposal of the College of Physicians to

admit into their body all graduates of British Universities on payment of certain fees, is not just towards the general practitioner, inasmuch as he was submitted to as severe a test of capability as the graduate of a Scotch University, and should therefore be equally privileged: again, they who would attempt to level the enlightened physician with the apothecary who vends his pennyworth of salts or jalap, are equally unjust. For a uniform code of examination and governing laws, I am a decided advocate, and would propose that all candidates twenty-one years of age, on producing the requisite testimonials, and passing an examination which would guarantee their possession of a good literary and sound medical and surgical education, should receive the degree of M.B. qualifying them for the *general practice* of the profession.

That Candidates of the age of thirty, possessing the above-named degree of M.B. or one from a British University, should undergo an examination in *practice of medicine* and general medical literature, of such a character as to exhibit matured views of the science, and receive the degree of M.D. qualifying them to practise as physicians throughout Great Britain. I might have enlarged much on this subject, but I trust I have sufficiently explained my views, and remain,—Your obedient servant.

A GENERAL PRACTITIONER.

Notting Hill, April 5, 1841.

UNIVERSITY OF CAMBRIDGE.

Regulations respecting Candidates for a Licence ad practicum in Medicina, and also respecting Candidates for the Degree of Doctor of Physic.

1. That Candidates for a Licence *ad practicum in Medicina*, being previously Bachelors of Physic, be required to produce to the Regius Professor of Physic Certificates of their having attended on Hospital practice for three years exclusive of the nine Terms which they kept by residence for the Degree of Bachelor of Physic, and of their having attended Lectures on the following subjects; namely—

Practice of Physic and Pathology.

Anatomy and Physiology.

Chemistry.

Botany.

Medical Jurisprudence.

Materia Medica and Pharmacy.

Principles of Surgery.

Principles of Midwifery.

Practical Anatomy for two seasons.

2. That Candidates for a Licence *ad practicum in Medicina*, being previously Masters of Arts, be required to bring satisfactory

evidence to the Regius Professor of Physic of their having been employed in the study of Physic for five years after they became Bachelors of Arts; and to produce to him Certificates of their having attended on Hospital practice for three of the said five years, and of their having attended Lectures on the subjects before mentioned.

3. That every Candidate for a Licence *ad practicum in Medicina*, be required to pass an Examination to the satisfaction of the Regius Professor of Physic, the Professor of Anatomy, the Downing Professor of Medicine, and a Doctor of Physic to be nominated by the Vice-Chancellor and approved by the Senate at the first Congregation after the tenth of October in each year.

4. That in case any of the three Examiners *ex officio* be prevented by illness or absence from taking part in such Examination, it be competent to him to appoint a Doctor of Physic to examine in his stead, subject to the approbation of the Vice-Chancellor.

5. That there be two such Examinations in every year: one in the week immediately preceding that in which the division of the Michaelmas Term falls: the other in the week immediately preceding that in which the division of the Easter Term falls.

6. That a Candidate for a Licence *ad practicum in Medicina*, being previously Bachelor of Physic, shall not be examined for the said Licence until the Examination which shall occur next but one after his having passed the Examination required for the Degree of Bachelor of Physic.

7. That every Candidate for the Degree of Doctor of Physic, who has not previously obtained a Licence *ad practicum in Medicina*, be required to produce to the Regius Professor of Physic the same Certificates and pass the same Examination as are required in the case of Candidates for a Licence *ad practicum in Medicina*.

8. Provided that the foregoing Regulations shall not take effect, until after the end of the Easter Term 1841; provided also that the seventh Regulation shall not apply to any person who was admitted *ad intrandum in Medicina* before the Lent Term 1836.

April 1, 1841.

VACCINE REPORT.

Feb. 1841.

To the Rt. Hon. the Marquis of Normanby, Her Majesty's Secretary of State for the Home Department.

MY LORD.—The small-pox has prevailed epidemically with considerable severity since our last report; but we do not abate an iota

of our confidence in vaccination as the best protective against its malignant influence.

We have vaccinated from this station alone 15,588 persons within the last year, which exceeds the number in any former year by 2,441, and have sent out to our correspondents at home and in the colonies 165,395 charges of vaccine lymph; and we feel considerable satisfaction in being able to state that the matter we employ is obtained by succession from the original virus communicated by Dr. Jenner himself, and that we find it as effectual as ever. We may be excused, therefore, we hope, if we discourage an incautious dissemination of matter obtained from new sources, which has not stood the test of an ample experience.

HENRY HALFORD,

President of the Royal Coll. of Physicians,
and of the Vaccine Board.

JOHN P. VINCENT,

President of the Royal College of Surgeons
in London.

JOHN BRIGHT, M.D.

Senior Censor of the Roy. Coll. Physicians.

CLEMENT HUE, M.D.

Registrar.

LECTURES
ON THE
PRINCIPLES AND PRACTICE OF
PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

LECTURE XXX.

Apoplexy continued. Relations between the symptoms and the appearances found in the brain after death. Exciting causes. Treatment.

I LEFT off in the last lecture, after having described the appearances met with in the head, at different periods after an attack of cerebral hæmorrhage; and pointed out the various sources of the hæmorrhage; and endeavoured to explain why it happens that the blood so much more commonly proceeds from a ruptured vessel in or near the corpus striatum and optic thalamus, than in any other part of the brain.

Relations between the symptoms and the morbid appearances.—I have already anticipated, in some degree, the account that may be given of the connexion which subsists between the morbid appearances, and the symptoms. I shall proceed to touch upon certain points, relative to that connexion, which have not yet been noticed.

One of the most remarkable circumstances which dissection teaches us, when there has been partial palsy, is, that the palsy is on *one* side of the body, and the hæmorrhage of the brain on the *other*. This is a very general law. But exceptions to it are said to have been observed. Morgagni mentions such. Dr. Bright has recorded a somewhat doubtful case of exception. I have never met with any: and I cannot help suspecting that a some of those which are said to have occurred, mistakes have been made: that either they have been incorrectly observed,

or inaccurately described. You may consider the rule as almost, if not altogether, universal.

This crossing over of the morbid effect of the extravasated blood, or of any other diseased state, has long been supposed to be satisfactorily explained by that crossing over of nervous fibres which takes place at the upper part of the spinal cord. Just where the medulla oblongata and the medulla spinalis unite, the anterior pyramids decussate each other, and send their fibres mutually to the opposite side of the body. All this of course you know. The right anterior pyramid is continued into the centre of the left half of the spinal cord; and the left anterior pyramid into the centre of the right half of the cord. Now supposing, as we have every reason to suppose, that the nervous influence, whatever may be its nature, travels in the course of the fibres of the brain, we see in this decussation of the anterior pyramids an easy and pleasing solution of the phenomenon in question. But then comes this serious difficulty. How does it happen that the muscles of the *face* and *tongue*—which are supplied by nerves that arise from the brain *above* the place of decussation—how does it come to pass that *these* muscles sustain the same cross injury, and are paralyzed on the same side on which the limbs are paralyzed? And again, how does it happen (as it certainly does) that hæmorrhage into the *cerebellum* should have a similar cross influence?

I am not aware that any one has undertaken to explain this anomaly, except Mr. Mayo; and his conjectures upon the subject are so recent, and some of them so ingenious, and some them, in my opinion, so erroneous, that I cannot do less than touch upon them here.

He takes some pains, in the first place, to shew that the morbid influence is communicated from one side of the brain to the limbs of the other side of the body, by means of the fibres of decussation already

described. This point did not, I think, require any laboured demonstration; but he has made a happy use of two facts previously ascertained, which, taken together, afford a very neat proof that the transference of the morbid influence from one side to the other actually takes place in that very part of the nervous system where the decussating fibres cross. The facts are stated by Dr. Yelloly, in the *Medico-Chirurgical Transactions*. Sir A. Cooper divided the right half of the spinal cord of a dog in the space between the occiput and the atlas; immediately, that is, after the cord has emerged from the skull through the foramen magnum: the result of this division of the cord was hemiplegia, paralysis of the limbs, on the *same side* with the injury. The bridge by which the morbid influence crosses over must therefore be *above* that point. We have got a limit on one side. And a case observed by Dr. Yelloly gives us a limit on the other. He examined the head of a man who had died hemiplegic; and he found a tumor, as big as a filbert, imbedded in and pressing upon the *right side* of the *anular protuberance*. The palsy had existed on the *left side*. The bridge of communication must consequently lie *below* that point. It must lie, therefore, between the two points now indicated: *i. e.* it must be either in the medulla oblongata, or just at the junction of the medulla oblongata with the medulla spinalis. Now in this very interval, *and here alone*, a decussation of the nervous filaments is found to exist. There can be no doubt that the decussating fibres form the channel of communication.

Supposing (what I think very questionable) that the prevalent notion respecting the uses of the anterior and posterior columns is correct, Mr. Mayo next explains, more clearly than I have found it explained by any previous writer, that the decussation of the anterior pyramids accounts both for the palsy and for the anæsthesia, which are apt to accompany cerebral hæmorrhage into the opposite side of the brain; inasmuch as the decussating fasciculi, on plunging into the opposite column of the spinal marrow, strike into its *centre*; and implicate themselves nearly as much with the posterior, as with the anterior, *i. e.* nearly as much with what is thought the sentient, as with what is thought the motor portion of the cord. The wonder seems to be why the numbness is not more constant: why it is infrequent in comparison with the affection of the voluntary muscles.

Mr. Mayo holds that palsy does not result from "the interruption of the ordinary supply of nervous stimulation furnished by the brain"—for this reason, that in living animals the brain has been gradually removed, sliced away, yet sensation, and the power

of voluntary motion, have subsisted; and that instances of acephalous human infants, which have survived their birth, shew the medulla oblongata and spinal cord to be sufficient, *without the brain*, for the production of sensation and voluntary motion. He conjectures therefore that the immediate cause of the hemiplegia is "*a depressing influence, or shock, (a withering influence he elsewhere calls it) originating in the brain when in certain states of lesion, and propagated from it to the medulla oblongata and spinal marrow.*"

Now it can scarcely be doubted, at least I cannot doubt, that the inference here drawn from the movements observed in acephalous monsters, and in animals after amputation of their brain, is a wrong inference. They are purely automatic movements, independent of sensation and of the will, and derived from the reflex endowment of the cord: and if this be so, the main foundation of Mr. Mayo's argument is cut away. For my own part, I have no faith in any *shock* except *pressure*. But mere pressure Mr. Mayo repudiates, asserting that in many cases of hemiplegia from cerebral disease there is *no pressure*. And this may be granted: although even in cases of softening, such as he refers to, the mere absence of support in some parts of the brain may lead to the subsidence or settling down of other parts, so as to cause pressure upon the medulla oblongata. I took some pains, in the course of the last lecture, to shew you that pressure is adequate to the production of coma and *general* paralysis; and pressure on a nerve in its course we are sure is capable of occasioning *local* paralysis; and upon the whole, my doctrine of the production of palsy by cerebral hæmorrhage or cerebral disease is, that it is frequently (not always) owing to the benumbing influence of *pressure*. I do not ask you to adopt that opinion; nor do I think the solution of the question is of any primary importance; yet I place the question before you, as the best way of impressing upon your memories the *facts* which it involves.

Now whether Mr. Mayo's notion, that some "*shock*" or "*withering influence*" is transmitted from the injured brain, be true; or whether that which I have proposed to your notice, *viz.* that this influence is no other than the benumbing influence of pressure, be true; either supposition will plausibly account for these facts, *viz.* that "in general hemiplegia from cerebral lesion, the palsy of the leg is (commonly) less complete, and is sooner recovered from, than palsy of the arm," and that when one of these limbs only is affected, it is (commonly) the *arm* alone. The shock, or the pressure, will be most felt in proportion as the part is nearer the origin of the pressure; and less

and less felt in proportion as we recede from the source of the injurious influence.

But, unfortunately, I was obliged to insert the word (*commonly*) in the statement just made of the *facts*; which word Mr. Mayo does not employ. To make either his theory, or the theory of pressure, perfectly satisfactory, either the arm alone should be affected; or the affection of the arm should always accompany and be more intense than, or at any rate not less intense than, the affection of the leg. But this is not the case. Since Mr. Mayo's observations were published, I have met with two or three cases, and pointed them out to him, in which the leg alone, or the leg first, has been palsied, from cerebral disease. And Andral, among 75 cases of cerebral hæmorrhage collected for another purpose, which I shall presently advert to, met with 12, in which the leg only was affected. It is a great pity that these stubborn facts should thus cross and thwart a very pretty theory. Perhaps they may hereafter be found not in reality inconsistent with that theory; but at present they are a sad stumbling-block in the way of our adopting it.

I will venture, in my turn, to suggest a conjecture by which the apparent inconsistencies may perhaps be reconciled. I think the excepted cases may be probably accounted for upon the very theory which Mr. Mayo rejects; viz. that the paralysis proceeds, in these cases, from a simple interruption of the nervous influence, a breaking up of the road by which the changes leading to sensation travel in one direction, and the mandates of volition in the other. We may easily conceive that, without any pressure, the conducting fibres of communication between the sensorium and the muscles of the leg may *alone* be torn across, or severed by a process of softening, while the residue of the conducting apparatus is entire: and I think it may be worth your while to note, as future opportunities for observation occur, whether the cases that fall within the general rule are not cases of hæmorrhage, in which there is a palpable cause of pressure; and whether what are now called anomalous cases are not cases of mere *softening*, without any obvious compressing agency.

I must not omit to give you Mr. Mayo's explanation of the *other* difficulties to which I referred—viz. of the paralysis of the muscles of the *face* being on the opposite side from the injury of the brain; and of the hemiplegia being on the opposite side from an injury of the *cerebellum*. And having given you it, I shall leave it, without farther comment, to your consideration.

Mr. Mayo's words are: "Where the decussating fasciculi of the anterior pyramid plunge into the opposite half of the spinal marrow, they are implicated, in a wonderful closeness of inter-texture, with fibres, which,

in their upward course, bend towards the places of origin of the ninth and seventh, and of the eighth and fifth nerves of the palsied side. May it not be supposed that this interlacement may be a sufficient means of communicating the palsy influence to the *ascending* fibres, which are in close relation to the affected cerebral nerves?"

Again, "How is the fact to be accounted for, that hemiplegia of the opposite side is produced by lesion of one hemisphere of the *cerebellum*? I have little doubt that the following explanation of the phenomenon will eventually be proved to be correct. The fibres of the anterior pyramids pass through the pons varolii. The pons varolii consists in great part of filaments which issue from each hemisphere of the *cerebellum*. These filaments may easily be supposed to convey a depressing influence from the diseased hemisphere. But in their course they come immediately upon the filaments of the anterior pyramid of the same side; and they are so implicated with the latter, with such a singular closeness of reticulation, and often with so much that looks like an actual interchange of filament, that it is far from unlikely that they may transmit to the descending fasciculi of the pyramid a shock (*qu.* a degree of pressure), which may thence be communicated to the same part at which a *cerebral* lesion exerts its paralyzing force."

I will only say farther of this hypothesis, that if the explanation it furnishes of the facts in question be not the best and most satisfactory in the world, it is the best and most satisfactory that we *possess*: and that, at any rate, we may make use of it to bind those facts to our recollection, until some better theory shall be devised.

There is one very curious law asserted, by Andral, in respect to hæmorrhage of the *cerebellum*. If the blood is effused into one side of the *cerebellum*, and no where else, the palsy that ensues follows the general rule; it takes place in the limbs of the opposite side of the body. But supposing hæmorrhage to take place on one side of the cerebrum, and on the other side of the *cerebellum*, simultaneously: what then, think you, happens? Doubtless you would expect that there should be palsy on *both* sides of the body. Hemiplegia on the one side, from the effusion into the brain proper; hemiplegia on the other side, from the effusion into the *cerebellum*: double hemiplegia; that is to say, general palsy. But it is not always so, in fact. The cerebral affection seems to overpower and master that of the *cerebellum*. Whatever the explanation may be, the palsy has been found to occur on the side opposite to the lesion in the brain proper; and not to occur on the side opposite to the lesion in the little brain. This is a very singular fact, of which Andral relates

four or five examples. But I suspect that they will ultimately take their place among the "anomalous" cases. As facts multiply, the law will, I conjecture, be found to be a different one.

The complex structure of the brain, and the dissimilar consequences that ensue, in different cases, from its injury or disease, lead directly to the belief not only that the organ subserves several distinct functions, but also that separate parts or sections of it hold peculiar and definite relations with other portions of the body. Ingenious men have even attempted to settle these points experimentally. By wounding or removing various portions in succession of the cerebral mass in living animals, and comparing the results, they have endeavoured to assign to each portion its particular province and function. But, to say nothing of the remarkable differences which exist between the cerebral functions in man and in the inferior animals, there is an unavoidable source of fallacy common to all such experiments. We cannot reach the particular spot in the brain upon which the contrived injury is to be inflicted, without penetrating and hurting various other parts; and from these combined injuries (dangerous, indeed, and often fatal in themselves) arise symptoms which the experimenter may erroneously conclude to be characteristic of the lesion originally in his contemplation.

Much more accurate and satisfactory data for the determination of this interesting class of questions, would seem to be furnished by the spontaneous operation of disease, and especially of the disease we are now considering. The injury done to the cerebral substance by the eruption of blood is not less sudden, nor less mechanical, than in the experiments or contrived observations to which I have alluded. It is capable also, in many instances, of exact appreciation in regard to its extent; the parts which lie round the seat of the effusion remain undisturbed; and above all, the organ that is the subject of our observation is the *human* brain itself.

Attempts have accordingly been made to connect particular symptoms with the disorganization of particular parts of the brain. These attempts can boast, as yet, it must be confessed, but little success. Very few, if any, of the conclusions hitherto advanced upon this intricate subject can be relied on. Yet it is proper that you should be informed of them.

Because palsy of the arm is, in general, more complete, and more persistent, than palsy of the leg, it has been maintained that the former, the paralysis of the arm, is to be ascribed to hæmorrhage of the *corpus striatum*, which seems to be more common than any other; and upon similar grounds

hæmorrhage of the *optic thalamus* has been supposed to determine paralysis of the *leg*. So much have these distinctions been confided in, that the honour of having first pointed them out has actually, in France, been made a subject of dispute. Now it is plain that one example of the contrary effect of these particular lesions, would suffice to upset the whole theory: but *many* such exceptions have, in fact, been noticed. It was with the view of settling this question that Andral collected and collated the 75 cases of cerebral hæmorrhage to which I lately referred. In each of these 75 cases the clot of blood was sufficiently limited to allow of that case being applied towards the solution of the controverted points.

In 40 of the 75, both the leg and the arm were paralyzed together. And where was the place of the hæmorrhage in these 40 cases? Why, in 21 of them the corpus striatum was the only part injured; and in 19 of them the optic thalamus was the only part injured. Thus you see, according to the theory just explained, in about one-half of these cases the arm alone *should* have been palsied, and in about *half* the leg alone: whereas both leg and arm were palsied in them all.

Again, in 23 of the 75 cases the palsy was confined to the arm. Therefore, according to the theory, the injury should have been confined to the corpus striatum. What was the fact? Why, in this class of cases also there was as nearly as possible an equal sharing of the injury between the two parts: in 11 of the 23 the corpus striatum alone suffered; in 10 the optic thalamus alone; in two the space between them.

Once more: there were, as I stated before, 12 out of the 75 cases in which the leg alone was palsied. Consequently, in all of these 12, if the theory were sound, there should have been damage of the optic thalamus only. But in 10 of them the mischief was confined to the corpus striatum; in 2 only to the optic thalamus.

Gall had conjectured that the faculty of speech was placed under the governance of the anterior lobe of the brain: and Bouillaud has endeavoured to support that opinion by a number of facts observed in connexion with cerebral hæmorrhage; but Cruveilhier has brought forward several curious instances in which the loss of speech was a prominent symptom, while the disease was *not* found in the anterior lobe, but in some other part of the brain.

Andral, with his accustomed industry, has accumulated evidence upon this point also.

In 37 cases of cerebral hæmorrhage observed by himself or by others, in which the morbid condition occupied one or both of the anterior lobes, the power of speech was abolished 21 times, and unaffected 16 times.

On the other hand, he has collected 14 cases, in which the power of speech was lost, yet no alteration had taken place in the anterior lobes. In 7 of these 14 cases the lesion was situated in the middle lobes; and in the other 7 in the posterior lobes of the brain.

There can be no doubt that there are certain distinct parts of the brain which influence respectively the upper and lower limbs; inasmuch as they are often separately palsied: and since the loss of speech is occasionally the only, or the most prominent symptom, while in other cases the speech is not affected at all, we cannot but believe that this faculty is under the special guidance of some definite part within the cranium. But the facts that I have just been quoting, shew, in the most convincing manner, that we are not able, as yet, to allot these separate functions to their proper spots in the cerebral mass.

Exciting causes.—I dwelt some little time, in a previous lecture, upon the circumstances that give *warning* to the patient, or to his physician, that the former is in danger of being smitten with apoplexy. And the great use of being acquainted with these circumstances, and of looking out for them, consists in the opportunity and the *authority*, which they furnish, for enforcing, upon the person in whom they manifest themselves, the absolute necessity of avoiding all the avoidable *exciting* causes of the disease. But our means of advising him will be very imperfect if we have not carefully considered what these exciting causes are. I propose to devote a few minutes, therefore, to the consideration of the circumstances that are apt to *bring on* the attack. There are many cases of apoplexy in which we cannot trace the operation of *any* such causes: but in many other cases their influence is decidedly marked; and the avoidance of them, while it is important to all who shew a disposition to apoplectic disease, is especially so to those who having once suffered an attack, have reason to dread a *repetition* of it.

In the first place, any thing which is calculated to hurry the circulation, and to increase the force of the heart's action, is likely to operate as an exciting cause of apoplexy: simply by augmenting the momentum of the blood against the sides of the cerebral vessels, which in advanced life are so often diseased and weak. Strong bodily exercise therefore is a thing to be avoided by all persons in whom the predisposition to apoplexy has declared itself. It is of much importance to make patients aware of this; for many persons think, when they labour under uncomfortable bodily feelings of any kind, they may get rid of them by a brisk walk; or by galloping some miles over the country on horseback.

Another dangerous state for such persons arises whenever the free escape of the blood from the head is suddenly obstructed. I have adverted to this before. Certain diseases, chiefly thoracic, which tend to keep the veins of the head inordinately full, rank among the *predisposing* causes of apoplexy. But, upon the very same principle, various conditions, which are temporary only, may operate as *exciting* causes. By what is called "holding the breath," whether upon an inspiration or expiration, the transit of the blood through the lungs is impeded: and the check is felt (through the pulmonary artery, right chambers of the heart, and great veins) in the vessels of the head. And this effect is increased when *straining* is at the same time performed; that is, when a deep breath is taken and retained, while some muscular forcing effort is made.

Under this principle fall a number of bodily acts, which, however harmless in a healthy frame, are not without peril, to a person having a predisposition to apoplexy. The motion of the blood in the lungs, and therefore in the head, is checked in the acts of coughing, vomiting, sneezing, laughing, crying, shouting, and so forth. You cannot have looked at a person in a violent paroxysm of coughing without seeing that it produced a determination of blood to the head, or rather a congested state of the veins of the head. The jarring pain in the head which is apt to follow each succession of the cough depends upon this principle: which is often strikingly exemplified in young children labouring under whooping-cough. They turn purple in the face, and become giddy; and not uncommonly ecchymosis of the conjunctiva occurs, giving fearful evidence of what might just as well take place *within* the cranium. It is not very unusual for the whole of the white part of the eye to become suddenly blood-shotten in these violent fits of coughing; and convulsions even happen under the like circumstances.

Straining at stool is a common exciting cause of apoplexy in those who are predisposed to it. And this is one of the worst dangers attending costiveness of the bowels in old people: but it is one which it is often in our power effectually to obviate. It is more within our control than a bad cough could be. Any kind of straining indeed is equally perilous. A very good illustration of this danger was recently afforded by a patient of my own. He was attacked with apoplexy on his way to Ascot races; and upon recovering somewhat, was found to be paralytic on one side of the body. He was brought back to town, when I saw him. After some time he regained the power of using the affected limbs to a very considerable extent; so as to be able to walk about, and follow his business, which was that of a job-master, or proprietor of a livery stable. I

cautioned him seriously, *inter alia*, against straining: but I suppose he forgot my caution. For, when getting up one morning, he tugged violently in attempting to pull on a damp boot, and in the midst of his efforts fell back insensible: and from this relapse he never fairly recovered.

To the same principle are to be referred a variety of things which a patient, in danger of this disease, must most carefully avoid. Lifting heavy weights; leaping; striking a hard blow; playing on wind instruments; even long and loud talking. Dr. Abercrombie relates two instances of fatal apoplexy brought on (as it would seem) by a sustained exertion of the voice: one of the attacks happened to a clergyman during the delivery of his sermon; the other to a literary man while speaking in a public assembly. In both cases a large quantity of blood was found extravasated within and upon the brain. Dr. James Gregory used to mention a patient of his, an officer in the army, who had apoplexy, and in whom the attack had been preceded by pains of the head, and giddiness, upon his giving the word of command, and particularly when dwelling upon the last sound; that is, when he made a long expiration. Precisely of the same kind is a case told by Van Swieten, of a singer who was obliged at length to abandon her vocation by reason of gradually increasing vertigo whenever she had to hold a high note. Violent emotion is another exciting cause. Large fires, crowded rooms, the heat even of the sun, will tend to produce apoplexy, and therefore ought to be shunned by those who have a tendency to that disease. The warm bath is not without hazard to such persons. This is so well known, I understand, at Bath, that the physicians there will not allow paralytic patients, in whom the paralysis has been connected with apoplexy—hemiplegic patients, for example—to go into their hot baths. The excitement of drunkenness, and the venereal excitement, are not uncommon causes of apoplexy, especially in old persons. I had a man of middle age under my care during the spring of 1837, in whom a most awful attack of apoplexy came on under circumstances just as I have now referred to. He had dined at a large festive party, and afterwards accompanied a woman with whom he was acquainted to a brothel; and he was struck with palsy during the act of intercourse. He was long unable to speak; and he still remains, and probably will ever remain, a cripple; imperfectly hemiplegic.

I have been since consulted upon the case of an old gentleman residing in France, in whom an attempt at sexual connexion was attended with similar consequences.

“The Gods are just, and of our pleasant vices
Make instruments to scourge us.”

Posture again has no small effect upon

apoplectic people. Giddiness, and some degree of confusion of thought, are apt to be occasioned in most persons by long stooping. There is one peculiar posture or position mentioned by Dr. Fothergill as being very unsafe, especially for short-necked persons—viz. that position which is assumed when we turn the head to look backwards for any length of time without turning the rest of the body; in fact, a twisting of the neck. In this action the jugular veins are more or less obstructed. He gives an account of a man who was seized with apoplexy as he was crossing the Thames in an open boat; he having kept his eye fixed upon a particular ship until, and after, he had been rowed past her. On the very same principle tight ligatures worn about the neck, and compressing the jugular veins, may bring on apoplexy; the wearing a tight neckcloth, for example. A continental writer informs us that a Swedish officer, who was desirous that his men should look well in the face, caused them to wear tight stocks; and the consequence was that in a short time a great many in that regiment died of apoplexy. Dr. Abercrombie quotes from Zitzilius the case of a boy who had drawn his neckcloth remarkably tight, and was whipping a top, stooping and rising alternately. After a short time he fell down apoplectic. The neckcloth being loosened, and blood drawn from the jugular vein, he speedily recovered.

There is one very powerful exciting cause of apoplexy, in those predisposed to it, which I need only refer to now, because the facts that have been observed in proof of its agency were fully detailed in a former part of the course; I mean exposure to cold. You will recollect my telling you that the number of deaths in London from apoplexy and palsy in the month of January 1795, which was a bitterly cold month, very much exceeded the number in the month of January 1796, which was a remarkably mild month. The cold operates in two ways, in the production of apoplexy. In the first place it drives the blood from the surface, and accumulates it in the large vessels of the interior of the body, and so increases the stress upon the cerebral arteries. And in the second place, the cold has a great influence in causing or aggravating affections of the *chest*; and the return of the venous blood from the head is impeded, in the manner just now explained, by fits of coughing and obstructed respiration.

This influence of external cold, and probably certain barometric conditions also of the atmosphere, help to explain, what I am sure I have several times had experience of, namely, the epidemic prevalence, now and then, of apoplectic seizures.

There is an alleged *exciting* cause of cerebral hæmorrhage, which I think it the more

necessary to consider, because I believe that very erroneous notions prevail about it, even among pathologists of eminence. I allude to the imputed dependence of cerebral hæmorrhage upon hypertrophy of the left ventricle of the heart. It has been supposed that the powerful contractions of a ventricle thus morbidly strong may drive forwards the blood with such unusual force, as to strain and burst the cerebral arteries. Dr. Hope, in his very complete work upon Diseases of the Heart, uses these words:—"Instances of apoplexy supervening upon hypertrophy have been so frequently noticed, that the relation of the two, *as cause and effect*, is one of the best established doctrines of modern pathology." And similar opinions are entertained by the most distinguished of the French writers on this subject; Andral, Bouillaud, Cruveilhier. I think they are all wrong: or that at least they state their proposition much too broadly, and generally.

I fully admit, no less from my own observation than upon the testimony of others, the frequent coincidence of hæmorrhage of the brain and hypertrophy of the left ventricle of the heart; but I distrust the reasoning which would always connect these events with each other as cause and effect. They may, sometimes, have that relation; but I have long thought that in most cases, if not in all, the coincidence is capable of being explained upon other and more satisfactory principles.

In the first place, hypertrophy of the left ventricle of the heart is very frequently, far more frequently than not, accompanied by other structural changes of that organ: changes which imply some impediment to the circulation; changes which involve or influence its right chambers also. In fact, disease of the right heart is not very often seen, without disease of the left; and one of the commonest forms of alteration to which the left side is liable, is hypertrophy of its ventricle. Now I have already pointed out to you the connexion which sometimes subsists between cerebral hæmorrhage and such disease of the heart as obstructs the ready and regular descent of the blood from the head through the veins. Many of the cases of apoplexy occurring in persons who have previously had cardiac hypertrophy are, I really believe, cases of this kind. The brain affection is dependent, in part, upon disease of the heart, but not upon the preternatural strength of its left ventricle. The heart acts morbidly upon the brain through the veins, and not through the arteries.

But there is another reason for the coincidence; and here the arteries are concerned.

No one can doubt that the momentum, with which the blood reaches the cerebral arteries, in *healthy* persons, under violent bodily exercise or mental excitement, must

often exceed the momentum produced by a hypertrophic heart in the cerebral arteries of persons who are tranquil and at rest. But apoplectic seizures are frequent under the latter circumstances, infrequent under the former. We must look, therefore, for something more than the mere hypertrophy to explain the coincidence. Now (supposing the absence of any check to the flow of blood from the head through the veins) that something is to be found in *disease* of the arterial system.

When the arteries of the brain are ossified, or changed, and rendered brittle in the way I yesterday described, the *commencement of the aorta* also is found, in a great majority of cases, to be the seat of similar alterations; and, often, to be sensibly dilated. Now the mere albuminous deposit beneath its inner tunic must seriously impair the elasticity of the vessel; and in this way the free passage of the blood out of the heart will be impeded; and the dilatation of the aorta at that part will produce the same hindrance more certainly and in a greater measure. Still more effectually and obviously will any contraction of the outlet prove an impediment. It is in consequence of these mechanical obstacles to the free exit of the blood from the left ventricle, that the walls of that chamber, urged to more vigorous contraction, become thicker and more powerful. The hypertrophy is the natural compensation for the morbid state of the aorta; without it the heart would much sooner become unable to propel its contents at all: and the hypertrophy does not often, I fancy, become greater than is needful for its purpose. The strength of the left ventricle, therefore, in such cases, is not a true measure of the force with which the blood is driven into the distant arteries. Quite the contrary. It is a measure of the *difficulty* with which the blood is circulated through the *primary branches*, and therefore through the entire system of the arteries. It indicates the *diminished* force with which the blood is likely to reach the cerebral vessels. And in point of fact you will find in *many* cases of hypertrophy of the left ventricle—I do not say in all, but certainly in very many—you will find the pulse at the wrist to be disproportionately small and feeble. So that, in these cases, instead of regarding the cerebral hæmorrhage as the *effect* of the hypertrophy (acknowledging, as I do, the frequent coexistence of these morbid conditions) I have been accustomed to look upon the apoplexy and hypertrophy as *concomitant effects of the same cause*; viz. of disease pervading the arterial tree. The hypertrophy of the left ventricle is the effect of the diseased condition of the aorta at its mouth; the cerebral hæmorrhage is the effect of the same diseased condition of the arteries in the brain.

When you find each of these lesions, and nothing to retard the venous current, you may, I believe, safely apply this explanation of the occurrence of apoplexy.

Having again referred to the frequent existence of disease in the cerebral arteries as a predisposing cause of hæmorrhage within the brain, I will just point out, before I leave this part of the subject, the light which that fact throws upon the circumstance that sanguineous apoplexy is so peculiarly a disease of advanced life. Earthy concretions in the coats of the arteries are so frequent in the later periods of existence, that they are met with, according to Bichat, in seven individuals out of ten of those who die beyond the age of sixty: and Dr. Baillie considered ossification to be much more common in old persons than a healthy state of the arteries.

Prognosis.—In the account which I have endeavoured to give you of the symptoms of apoplexy, of the different modes in which the attack may commence, and of the various morbid appearances discovered within the cranium in the fatal cases, I have already embodied almost all that can be stated, with any confidence, respecting the special diagnosis and the prognosis of the disease. The one of these follows the other: the exact diagnosis being known, the prognosis is seldom difficult. By the diagnosis, however, I do not now mean simply the recognition of the disease as a case of apoplexy: of that *general* diagnosis, of the means of distinguishing the coma of apoplexy from the coma caused by opium or alcohol, I told you all that I know in a former lecture. But I use the term diagnosis now in a stricter sense, and in reference to the distinctions that exist between *one case* of apoplexy and *another*; and I say that in proportion to the accuracy with which we may be capable of determining the precise condition of the contents of the skull, will be the facility of predicting the issue of the complaint. Let me remind you, then, that when a patient suddenly becomes apoplectic, we cannot tell whether there be effusion of blood, or effusion of serum, or no effusion at all within the cranium: and therefore the diagnosis must be precarious and uncertain. If, after the use of suitable remedies, the coma persists for many hours, the prognosis becomes worse. In those cases which begin with pain of head, faintness, and nausea, and which pass on to coma, the prognosis is positively bad; for the diagnosis is easy, and we are tolerably certain that a blood-vessel has given way, and that a large quantity of blood has ploughed up the substance of the brain. In the paralytic cases also, if coma supervenes, the prognosis is gloomy: but frequently coma does not supervene, and then our prognosis, as far

as life is concerned, may be pronounced favourable.

Among the symptoms that belong to the apoplectic condition itself, there are some which experience has selected as being most especially of evil omen: and it is well worth your while to remark that these discouraging signs relate, almost all of them, to the automatic functions of the cranio-spinal axis. The open, fixed, unwinking eye; the explosive flapping of the cheeks in expiration; the inability to swallow; the slow, sighing, interrupted breathing; the loosening of the sphincter muscles of the bladder and anus; these are fatal symptoms, and these all depend upon the excito-motory portion of the nervous system. Perhaps the profuse sweat that so often attends the process of dissolution may be referred to the same source; the whole tone of the various tissues being lost or relaxed. I would not say that no one of these symptoms is ever recovered from: but I may say that of twenty patients in whom such phenomena occur nineteen will die.

Now symptoms of this kind may be expected to arise, if there be hæmorrhage in or near the medulla oblongata; or if there be mischief so extensive in the brain as to cause pressure upon the medulla oblongata. We should reason out the likelihood that such symptoms would be of bad augury. But the fact that they are so was ascertained long before the theory which accounts for them was devised. The fact is independent of the theory, and for that reason helps wonderfully to confirm it.

Treatment of apoplexy.—The older writers entertained some very false notions in respect to the distinction between sanguineous and serous apoplexy. They laid it down that apoplexy resulting from extravasation of blood within the cranium was denoted by flushing of the face, and strength of the pulse; and that it was a disease of persons in the vigour of life: while apoplexy resulting from the effusion of serum was marked by paleness of the countenance, and weakness of the pulse; and occurred in the old and the infirm: and they directed their practice according to this distinction. After what has already been said, I need not tell you that this classification of apoplexies could not have been founded upon the actual observation of disease: and that our treatment, now a days, is not regulated by any such erroneous theory.

Nevertheless, I do not mean altogether to praise the modern practice in apoplexy; for it is often one of mere routine. Practitioners are very apt, in this as in other instances, to be guided in their choice of remedies by the *name* of the disease, and to treat all cases of apoplexy alike. I remember being

much amused by the perplexity which a friend of mine once told me he had felt on being summoned by letter many miles into the country to see a gentleman who had been struck with apoplexy. As he posted down he earnestly revolved in his mind what he might be able to advise when he should reach the house of sickness. He felt confident that the patient must already have been copiously bled; cupped, or leeches; blistered; and thoroughly dosed with calomel, senna, and croton oil. Mustard poultices had doubtless been applied to his legs. My friend was distressed to think that while much would be expected, nothing would be left for him to do worthy of so long a journey, and so heavy an expense to the patient. A clyster of turpentine might yet, perhaps, be an untried expedient. His cogitations were cut short, however, and his cares relieved, by an express which met him half-way on the road to announce that the patient was dead. Now this is the routine of which I speak: most proper in many cases; unnecessary in others; pernicious in some. There are persons who seem to think that they have not done their patient justice if any part of this active intermeddling has been omitted. Others regard depletion as being worse than useless, and trust entirely to stimulants and cordials. These are still more dangerous *routiniers* than the others: but they are fewer in number.

Our practice would indeed be much easier than it is, if we could thus make one plan fit all cases which are, nominally, the same. But I need not, now, tell you that diseases alike in name—aye, and alike in their essential nature—are often widely different in their circumstances. I formerly explained to you that certain symptoms tell us what the disease is; but that we are often obliged to look to other symptoms, which may tell us what we are to do. I know of no rule so likely to guide you aright as that laid down generally by Cullen, of *obviating the tendency to death*. You must examine and judge to which of the several modes of dying there may be any obvious approach. If the tendency be, as in cases of apoplexy it mostly is, to death by *coma*, then blood-letting and the evacuating system will be requisite. If, on the other hand, the tendency be to death by *syncope*, you must withhold the lancet, and even have recourse to stimulating and restorative measures. Now the distinction between these modes of dying is to be made by attending to the state, not so much of the nervous, as of the sanguiferous system. Insensibility and unconsciousness are common both to syncope and to coma: and cases which fall under the class of apoplexies, and which we cannot separate from that class, are sometimes really more like cases of concussion than any thing else; the shock having

been of internal instead of external origin. If the pulse be full, or hard, or thrilling (sometimes it feels like a tense vibrating rope), or if there are obvious external signs of plethora of the head, you must abstract blood. You are not to refrain from bleeding the patient because he is pale, if his pulse warrants it: nor may you omit taking blood if the head and face be turgid, although the pulse be small; for that smallness may depend upon organic disease of the heart.

On the contrary, if his skin is pale and cold, and his pulse feeble or flickering, you would probably ensure your patient's death, or determine the accession of palsy, if you withdrew from the failing heart and blood-vessels a portion of their natural stimulus. I can only invite your attention to these broad features of distinction. Being once taught to look for and attend to them, your own judgment must instruct you as to what may be needful in particular cases. To this, as to most other diseases, the remark of Boerhaave is strictly applicable, who declares that he knows of nothing which can be called a *remedy*. "*quin solo tempestivo usu tale fiat.*"

Having made up your mind as to the general indications of treatment, you will pursue them steadily in detail. If the patient to whom you are summoned be stupid and drowsy rather than faint, and his pulse and appearance warrant the conclusion of plethora capitis, the first thing to be done is to place him in a semi-recumbent position, with his head raised; to loosen any tight parts of his dress, especially his neck-cloth and shirt collar, and whatever might press upon the *neck*; and then as quickly as possible to bleed him from the arm. We know that in some cases the apoplectic state occurs, when as yet no injury has been done to the brain; no effusion, no laceration of its texture; and we may hope, by timely and vigorous measures, to *prevent* these terrible evils. We never can be sure that there is blood extravasated in such cases, and we must act, in the first instance, upon the presumption that there is not. We are especially encouraged to take away a considerable quantity of blood by venesection when we perceive external signs that the vessels of the head are full; redness and turgescence of the face, throbbing and prominence of the temporal arteries, distension of the superficial veins of the neck and forehead. Our object is to take off the strain upon the internal vessels, by bleeding in such a manner and to such an amount as shall produce a decided effect upon the general circulation. Sometimes the good effect of the bleeding is very marked indeed, so that no doubt of its propriety can be entertained; the patient being so insensible as not to feel the puncture of the lancet, and yet

emerging from his coma while the blood is still flowing. It is seldom, however, that we can expect such manifest and immediate melioration as this.

After one *sufficient* bleeding from the arm, the vessels of the head may be farther relieved by cupping the nape of the neck, or the temples; and venesection may be repeated if the condition of the pulse, and of the symptoms generally, should require its repetition. It is seldomer, however, in cases of apoplexy than in cases of acute inflammation, that a second or third recourse to the lancet becomes advisable: unless, indeed, the first blood-letting has been mismanaged. Enough blood must be taken, in the first instance, to produce some evident effect; and therefore no precise rules can be laid down in regard to the absolute quantity to be drawn; nor can we make any estimate beforehand as to the whole amount of blood which it may be necessary to remove.

Even if we could be sure that a blood-vessel had given way, and blood was already poured out upon the brain, there are good reasons why (no adverse circumstances withstanding) we ought to bleed our patient largely, and at once. I will enumerate briefly the benefits we seek to obtain by the abstraction of blood in such cases.

1. The effusion from the ruptured artery may be slowly going on. Bleeding from a vein, so as to make a sensible impression on the general circulation, will diminish the stress upon the cerebral arteries, and so tend to put a stop to the hæmorrhage. Both of these two objects are of primary importance.

2. By early and free bleeding we lessen the chance of inflammation supervening upon the mechanical injury done to the brain by the sudden tearing and confusion of its texture by the effused blood; and

3. We thereby bring the system into the most favourable condition for the rapid absorption of the extravasated blood, and for expediting the patient's recovery from those symptoms which depend upon the presence of the clot in the brain.

But although, in that form of disease which we are now considering, bleeding is our sheet anchor, it may be carried too far, or repeated too often. We must not lose sight of the fact that many of these patients are old, and will not survive over depletion; and that if they survive at all, they will need all the strength that we dare suffer them to retain for carrying on the vital actions, when the chief instrument of the most important of the animal functions is so greatly damaged: nor of the fact that if there be blood extravasated, we cannot touch it, except indirectly, by the abstraction of more blood from the arm: nor of the fact that a patient may be bled into convulsions, and fatal syncope. In short, after the first free bleeding, you must

be guided by the special circumstances of the case, and particularly by the pulse. The woman at present in the Middlesex Hospital, with paralysis of the limbs on one side, and of the face on the other, attributes her palsy (erroneously most likely) to her having been cupped. She had had a blow some weeks before, and suffered headache from that time. At length she was cupped, from the neighbourhood of the head; and the next morning she was paralytic. This might have been an accidental coincidence. But I remember being sent for a few years ago to see a patient, at Greenwich, who had already three physicians about him, and was apparently in danger of apoplexy, of which he had for some time experienced distinct warnings. The three physicians had agreed that he ought to be cupped from the back of the neck; to which I assented; and while blood was being rapidly extracted in that manner, he became all at once hemiplegic. Similar cases have been noticed by other persons. Therefore we are not to bleed without measure or discretion.

The pulse may be small, and the arterial action feeble, while yet the veins are turgid, and the capillaries of the head and face loaded with blood. Changes may have occurred in the heart, such as to obstruct the stream which it is its healthy office to transmit. These are cases to which the local abstraction of blood from the head by leeches and cupping glasses is peculiarly adapted.

Again, the whole state of the patient may approximate more or less nearly to the state of syncope; the pulse being weak, the aspect pinched and bloodless, and the skin cool. In this condition, no good, but much harm, is to be expected from blood-letting of any kind. You will do better to apply warmth, cautiously, to the surface, and cautiously to administer what are called diffusible stimuli, of which the preparations of ammonia afford the most eligible forms. Five grains of the sesquicarbonate, or half a drachm of sal volatile, mixed with camphor julep, are ordinary doses. Meanwhile you must carefully watch for symptoms of reaction.

In more ambiguous cases, when you scarcely can tell which way the balance inclines, I would advise you to wait the effect of the next remedy I have to mention; viz. purgatives, about giving which you need not entertain the same doubt and hesitation.

Purgative medicines are of signal service in apoplexy. They empty the intestines, which are oftentimes loaded, and which by distending the abdomen have perhaps occasioned undue pressure against the diaphragm, embarrassed the breathing, and through it the cerebral circulation. Another very important purpose of hard purging, which I have frequently pointed out before, is the pro-

ducing of copious watery discharges from the bowels; whereby the blood vessels are drained, and the tendency of blood to the head especially relieved. If the patient can still swallow, you may give him half a scruple of calomel, and follow it up by a black dose. If the power of deglutition be lost, the croton oil becomes a most valuable remedy. Dr. Abercrombie suggests that it may be conveniently introduced into the stomach, suspended in thick gruel or mucilage, by means of an elastic gum tube. But really this is not necessary. If two or three drops of the oil be put upon the tongue, as far back as is possible, it will produce its specific effect very readily and well. But we are not to wait for the operation of aperients given by the mouth. Strong purgative and stimulating enemata must be thrown into the rectum: half an ounce, or six drachms, of turpentine, suspended, by the help of the yolk of an egg, in gruel or warm water. We very often witness decided signs of amendment upon the free operation of a purgative. I may mention one instance of this while it is fresh in my recollection. I was asked, a few evenings ago by a medical friend, to see an old gentleman, a patient of his. I found him in bed, comatose, but capable of being roused when loudly spoken to: but he presently fell off again into stupor. His respiration was peculiar. For a minute or two he would breathe, snoring strongly; then the breathing would cease altogether for half a minute or thereabouts; and then the stertorous respiration recommenced: and so on alternately.

He had been found by his servant on the floor, nearly insensible, in the morning, having fallen either out of, or upon rising from, his bed. He had very properly been cupped; and calomel and aperient medicine had been given: but the coma had been growing more profound all the afternoon. His bowels had been but scantily moved; and the fæces and urine were passed as he lay. His extremities were coldish. The pulse was neither full nor strong.

I learned that for four or five years he had had some very significant warnings; and within that period had suffered one or two slight apoplectic seizures, which had left him with impaired mind and memory.

I recommended blisters behind the ears, and two drops of croton oil with two drachms of castor oil, in a draught. The next morning I expected to hear that he was dead; but I found him quite conscious, speaking somewhat inarticulately, with the right side of his face chapfallen and inexpressive. There seemed no particular weakness of the corresponding extremities. The oils had been followed by copious evacuations from the bowels. The day afterwards he was

sitting up, and so well, that I took my leave.

In combination with blood-letting and purgatives, cold lotions to the head are often found useful in this disease, especially if its surface is hot. I need not trouble you by rehearsing the modes in which the application of this remedy may be managed. Blisters near or upon, the head, are also frequently of service, after due abstraction of blood, in rousing the patient from his state of coma.

Formerly, at the suggestion, I fancy, of Dr. Fothergill, it was much the fashion to give an *emetic* in the outset of the treatment of apoplexy. But we can scarcely imagine that this was not a hazardous measure; and almost sure to do harm if there was already any extravasation of blood. I believe this practice to be now obsolete; and that very circumstance is a proof that it could not have been attended with much success. I merely mention it to protest against it.

When the immediate danger has passed by, and paralysis remains, we are not to be over busy. If the palsy is to get gradually well, it must be by virtue of time, and the resources of nature. To young and strong persons I should, under such circumstances, give small and repeated doses of mercury: and in all cases I should prescribe aperient medicines, so as to keep the bowels freely open twice or thrice a day; enjoin perfect quiet; and put the patient upon very short commons. Diuretics are also very proper when the urine is not plentiful without them.

You will often have to contend against the ignorance and impatience of patients, and their friends, on these occasions. They think that *weakness* is to be remedied by *strengthening* food; by meat and drink, and tonic medicines: or if they are not so foolish as this, they will want to be electrified, or to be put into a warm bath. Certainly in the earlier states of the palsy that remains after apoplexy, none of those measures ought to be *permitted*. If after some time, when all febrile action has ceased, the palsy seems stationary, it may be warrantable and right to attempt to stimulate the torpid nerves, and to accelerate the acquirement of power by the mind over the muscular contractions: but when any means for attaining these objects are employed at all, they must be used with the utmost caution; for they are much more likely to stimulate the vascular system, and so to do harm; or even to renew the apoplectic attack. Electricity, and strychnia, are the remedies most relied upon. In cases of long-standing palsy, it may also, no doubt, be of use to try to awaken, by stimulating frictions, the dormant powers of the muscles, which by protracted inaction become *forgetful*, as it were, rather than *inca-*

pable, of their natural office: and in these old cases we sometimes are able to benefit our patient's condition by the cautious exhibition of some of the preparations of iron.

AN ESSAY

ON THE

SOURCES OF TYPHUS OR CONTINUED FEVERS.

By JOSEPH BELL, Surgeon, Barrhead.

[Continued from page 98.]

TYPHUS is not the only febrile contagious disease which originates independent of fever, and propagates itself by this principle. We have that dreadful malady, puerperal fever, and also erysipelas, both originating from contagion in some instances, and arising independently of it in others. We perceive, then, that though there cannot exist a doubt, on the one hand, but that contagion is a source of typhus, yet on the other we see that it is highly erroneous—opposed to both analogy and fact, to maintain that it cannot be originated from any other source.

Let us proceed to examine the other sources from which it is said to arise.

1st. *Malaria*.—In the reports on the "Sanatory State of the Labouring Classes in and about London," the doctrine of the origin of fever is strongly maintained. The following is the conclusion which Drs. Arnott and Key have formed from the reports of the various district surgeons:—"Besides the malaria arising where nature is uncultivated, we find that wherever men congregate, and bring together the quantities of vegetable and animal substances which constitute their food, in the preparation of which there is much refuse, or where the excrementitious matters from their own bodies (being the matter of their food again rejected, and in another form) are allowed to accumulate, there is produced another malaria, often as destructive to life as the most active which dwells in the Indian jungle. The fevers called typhus, putrid, malignant, jail, hospital, ship fever, &c. are the products of this malaria, and, when once induced, the bodies of persons affected give out a contagious malaria, often more quickly operative

on other persons than the original cause."

Dr. Southwood Smith, in Supplement No. 2 of the Reports, states that "the exhalations which accumulate in close, ill-ventilated, and crowded apartments, in the confined situations of densely populated cities, where no attention is paid to the removal of putrefying and excrementitious substances, consist chiefly of animal matter; such exhalations contain a poison which produces continued fever, of the typhoid character."

Such, then, are the opinions of these physicians, founded, as has been already mentioned, on the reports of the district surgeons of London. But, as it has been justly observed, we live in a discriminating age—an era in which we are unwilling to adopt either the conclusions or opinions of others, without investigating the facts from which these conclusions are deduced, as well as the process of reasoning employed in their deduction. Let us take a brief survey of the reports:—

The district surgeon of Lambeth, after stating that fever prevailed to a considerable extent in that parish, observes, "The primary cause of this infection I believe to be the malaria, or effluvia, arising from the state of the drains, or stagnant filth: the heat of the sun, acting upon the mud, sends forth this kind of malaria, which, impregnating the air, is the first cause of fever."

Mr. J. Appleton mentions, that, in a part of the district of which he has medical charge, there is a large open ditch, filled with filth, and contaminating the atmosphere in and around the dwellings of the poor. He also observes, "that the majority of the cases of sickness occurring in this district are typhus and continued fevers. . . . Considering the privations many of them undergo with respect to food, and their intemperate use of ardent spirits; that they are huddled together in ill-ventilated rooms; and that this place is the resort of Irish lodgers, who are travelling the country, it is exceedingly difficult to give an opinion how far these cases of fever have had their origin in states of the atmosphere equally affecting the crowded parts of the metropolis, and how far they have originated in the local causes above named."

We are told by another surgeon that, in his district (comprising Homerton and Mare Street, of the Hackney Union), fever of a typhoid character is seldom absent. This, he thinks, arises from "an obstruction by a dam to a mill," which allows "a large accumulation of decaying and other matter of a deleterious nature, likely to cause an atmosphere not at all congenial to health, which, aided by, I am sorry to say, the innate want of cleanliness and care on the part of the poor, frequently gives rise to fevers of this description."

At page 19 of the Report, Mr. Foote states that, "two years past a fever raged at Red-Hill, which I attributed to the lodgment of the filth from privies, which I had removed at the time; and the same thing occurred at the Hyde, the fever prevailing there being of the typhoid type; and I consider that, unless the ditch is cleaned, the same kind of fever will prevail again; and also at the Marsh, in the parish of Great Stanmore, typhus fever lately prevailed amongst the poor."

Dr. Bowling states that, "at Hammersmith, fever has always prevailed at certain seasons among the poor, attributable in a great measure to miasma, produced by a quantity of water which had been left stagnant on the surface of the earth after brickmaking, and which, in process of time, had become full of vegetable matter."

Another report speaks thus, at page 21:—"Fever has been most severe in those courts and alleys where there is no circulation of air, such as, for instance, Johnson's Change, in Rosemary Lane, in which there are about twenty houses, in almost every one of which fever has prevailed. The disease first made its appearance there in August last." This is ascribed to the "intolerable nuisance of the overflowing of a cesspool or privy."

Another surgeon, at page 22, makes the following observations:—"The last six or seven weeks we have been called on to attend many cases of typhus fever, of a very malignant character, chiefly attacking the labouring classes residing in the dirty and most unhealthy portions of our locality. The majority attacked were those who were unable to procure adequate nutriment, from want of employment during the last inclement weather." He ascribes this prevalence of the disease to "the ab-

sence of cleanliness, crowded state of the houses, intemperance, accumulation of filth, slaughter-houses, sewers,—all these circumstances constitute the constant source of the generation of contagion."

Such, then, is the most recent evidence adduced in support of the origin of fever from malaria. The facts, however, merely prove that which is admitted by every person conversant with the practice of medicine, namely, that among the inhabitants of the ill-ventilated and filthy localities which are met with in large towns, fever prevails to an alarming extent—an extent wholly disproportionate to that which occurs among the better classes of society, who live in more airy and clean dwellings. I cannot conceive how the facts stated in the reports can be made to support any other inference. In the whole series of opinions and statements, there is no proof of a single case of typhus having originated from malaria. It is true Dr. Southwood Smith states that the formation of a common sewer, the filling up of a ditch, the removal of stagnant water, and the drainage of houses, have rendered a district healthy, from which, before such measures were adopted, fever was never absent. "This is strikingly exemplified," he further observes, "in the present healthfulness of the upper part of the Hackney Road, in which an excellent common sewer has been recently made, the neighbourhood of which is now well drained." (P. 36.) He further adduces a few similar illustrations. These circumstances, however, cannot affect the argument very much, when we take into consideration that these improvements were only of recent date, and that fever is very apt to shift its seat during epidemics. It should also be borne in mind, that improper ventilation is a very great cause of the propagation of contagion; that the poor creatures who dwell in these wretched abodes of filth and misery are in a condition highly favourable to the attack of typhus. Contagion having gained access to such hovels, will be propagated to a most fearful extent, from the number of causes which exist to favour its spread, and to increase its virulence. Hence contagion is just as likely to be the source from which fever originates in such instances as is malaria. But even putting these considerations alto-

gether out of view, there are many facts which strongly oppose the doctrine of the malarious origin of typhus. We have many instances of people exposed to the influence of malaria, of a much more intense and powerful nature than any effluvia which can possibly occur in our large towns. These people are not only in the enjoyment of good health, but are scarcely ever attacked with typhus fever.

I will merely remind you of the many facts detailed by Drs. Chisholm and Bancroft, in their writings on the subject—facts which afford powerful evidence against malaria being a source of fever. My time will only permit me to allude to the investigations of a more recent writer, now no more—I mean Parent-Duchatelet—a man of the most comprehensive intellect. He investigated this very subject with a degree of discrimination never surpassed.

At Montfaucon, in France, there is one of the most offensive manufactories that could possibly exist—a manufactory where effluvia of the most repulsive nature is daily elaborated, rendering the atmosphere insupportable for thousands of yards around the place. In this manufactory there are 12,775 horses slaughtered annually. The basins of this reservoir contain 32,500 yards of surface, and upwards of twelve acres occupied by dry matters. To this place, besides the twelve thousand horses, there are brought daily 240 cubic yards of human filth from the privies, and thirty thousand bodies of small animals, all of which are left to rot on its surface.

These animals are flayed up, and undergo various processes: the intestines manufactured into gut; some parts are made into manure; from others maggots are bred to feed poultry. Such are the disgusting operations which are carried on in this place. "In reality," observes Duchatelet, "nothing can be compared to the disgusting effluvia produced by these establishments." Let one figure to himself what may be produced by the decomposition of heaps of flesh and intestines, abandoned for weeks and months in the open air, and to the heat of the sun, to spontaneous putrefaction; let him endeavour to conceive the nature of the gases which can arise from the heaps of carcases that remain covered with much of the soft parts;

let him further add the emanations furnished by a soil which for years has been drenched with the blood and fluids of animals—those which arise from the blood itself, which in both the yards lies on the pavement without being able to make its escape—those of the kennels of the gut spinners and dryers in the neighbourhood; let one multiply as much as he pleases the degrees of stench, by comparing it to that which every one of us has been enabled to feel on passing near the bodies of animals in decomposition, which it was necessary to encounter, and but a feeble idea shall be formed of the truly offensive odour which emanates from this sink, the most offensive that it is possible to imagine.

Any malaria which can possibly arise from uncovered drains, crowded apartments, slaughter-houses, sewers, must sink into perfect insignificance when compared with that which proceeds from this awfully disgusting manufactory. If malaria be at all a source of typhus fever, the disease must here exercise the most dreadful malignancy. We have the evidence not only of Duchatelet, but also of Deyeux, Parmentier, Pariset, Damoiseau, and Huzard, that typhus fever is almost unknown among the workmen, who enjoy excellent health—even those who remain constantly in the tainted atmosphere. The three first-named gentlemen tell us that they found some of the workers in the best of health, who had not been off the premises for a year, and who slept in a place which they found impossible to enter, on account of the intensity of the fætor exhaled.

Duchatelet saw many of the workmen sixty and seventy years of age stout and active. "We have taken exact notes," says he, "respecting their fathers and mothers, and have learnt that they all died at a very advanced age, and almost always exempt from the infirmities of old age. He also found that new workmen were not subject to illness more than those who had been employed for years. Further, he states that those who are employed in the manufactory of a kind of manure called poridette, which is prepared from the filth procured at the privies, and is nothing more than dried ordure, enjoy the same immunity from typhus fever. In the report on the sanatory condition

of the labouring classes of London, we have heard the cause of fever ascribed to the overflowing of a cess-pool, the accumulation of animal and vegetable matter in a mill-pond; but in Paris Duchatelet informs us that the Bieore, a stream that runs through that city, is nearly dry in summer, and sends forth exhalations insupportable to those who pass in the vicinity: the mud, which is entirely composed of the remains of animal substances, swells when it becomes dry, puffs up, and bursts, like fermenting dough. The exhalations arising from this place are so intense that meat cannot be preserved more than a few hours during summer; and yet there are no typhus, putrid, or malignant fevers prevalent, among the thirty thousand individuals who are densely crowded together, in the part of the city through which this bed of putrescency extends. Duchatelet found the inhabitants of this place as healthy as those of the other parts of the city; and ascertained that they were not more liable to any serious disease than those who resided in other parts of Paris. If time permitted, many facts similar to those narrated might be adduced, proving the doctrine of the malarious origin of fever to rest on very slight foundation. Any evidence which has been brought forward by the advocates of this doctrine is entirely of a presumptive character, which, in my opinion, is completely overturned by the facts which I have quoted. There is, however, one circumstance which we must not overlook, namely that the condition of the workmen engaged at the disgusting employment to which I have alluded, and that of the people exposed to malaria in large towns, is not strictly analogous; the former are well fed, comfortably lodged and clothed, have plenty of animal food, though it be horseflesh; whereas the latter are badly fed—I should rather say half starved—miserably lodged; badly clothed, if clothed at all; and often of intemperate and abandoned habits. They are consequently not capable of sustaining the agency of any deleterious principle so well as people in the condition of the Montfaucon workmen. Hence it may be argued that malaria may exercise its malignant influence on the one, and not on the other. I think that this should rather lead us to consider a source of fever which the advocates

of malaria have either overlooked, or slightly glanced at, viz. privation, or, in other words, exposure to cold, want of food, and other necessities of life. This brings us to another part of our subject—the origin of typhus fever from privation.

We have seen, from the “Report on the Sanatory State of the Labouring Classes of London,” that fever was almost entirely confined to those parts of the city inhabited by the poor; that want of proper nutriment held a prominent feature in the character of those affected by the disease.

Poverty prevailed to a most alarming extent in Ireland during the years 1817, 18, and 19, when that country suffered so much from epidemic fevers. The harvests were bad, and the produce of the land was not properly matured, so that food was very deficient in quantity, and of unwholesome quality.

Drs. Barker and Cheyne state that from the year 1721 to 1728 there was scarcely a case of fever to be met with in Ireland. “After the latter year three bad harvests occurred in succession; provisions rose to an extravagant price. . . . From 1728 fever gained ground, and continued to be epidemical to 1732. The season following 1739 was one of great severity. Fever, which had been frequent, again became epidemical; it did not cease in the winter, and increased most alarmingly in 1741. Dr. O’Connell states that the mortality during this epidemic was 80,000. . . . The year 1800 was nearly as unfavourable to the fruits of the earth as 1799.’ Great scarcity prevailed. The price of bread and potatoes, both of bad quality, together with every necessary of life, was raised beyond all precedent. In the autumn and winter of 1800 the inhabitants of this kingdom suffered from a contagious fever, in which the troops still continued to participate. . . . The epidemic had reached to the most alarming extent at the commencement of the autumn of 1801. Shortly after this, however, it began to decline, “but not before the good effects of an unusually abundant harvest, in again furnishing provisions of all kinds to the poor at a moderate rate, had been felt.” In 1816, the harvest proved exceedingly bad. It was not only defective, but late. Much corn remained uncut, and a greater portion was only cut in Octo-

ber and November of that which was saved. The potatoe crop was a failure. Besides these calamities, fuel was scarcely to be obtained; and trees were stripped of their leaves and bark by the starving population for food; whilst the branches were used for fuel. The following year, 1817, was equally unpropitious; nor was 1818 much better. To these distressing circumstances were added the evils of commercial distress—extensive failures in trade, and lowering of wages. The following extract from Dr. Gratten will show the effects of this awful state of privation:—"The present epidemic," says he, "is principally to be referred to the miserable condition of the poorer classes in this kingdom; and so long as their state shall continue unimproved, so long will fever prevail; probably not to its present extent, but certainly to an extent sufficient to render it at all times a great national affliction. He also observes at another place, "Next to contagion I consider a distressed state of the general population of any particular district the most common and most extensive source of typhoid fever, whether this has been the result of war, or been produced by the more gradual progress of domestic misfortune."

Professor Alison, in his valuable work "On the Management of the Poor in Scotland," after describing (in a very graphic manner) the shamefully destitute condition of the poor in Scotland, alludes to the miserable state of the people in Ireland during the years 1817-18-19, as the source of the epidemic which ravaged Ireland at that period. He observes: "That it is always in persons suffering, or who have lately suffered, similar privations and sufferings, and the mental depression and despondency which naturally attend them, that continued fever becomes extremely prevalent, is fully established by the history of all considerable epidemics. The elaborate work of Drs. Cheyne and Barker shows that this has been strictly true of all the great epidemics which have appeared in Ireland since 1700; each of them lasting fully two years, viz. in 1708, 1720, and 1731, in 1740-1, (after the great frost in 1740), in 1800-1, after the rebellion; the transference of the seat of government to London, and the scarcity of 1799, 1800, and again in 1817, after the tran-

sition from a state of war to a state of peace, and the scarcity of 1816-17.

That work contains reports from the most eminent physicians in all parts of Ireland on that great epidemic, all agreeing in the statement that the poor were the greatest sufferers; and the fever seemed to rage among them in a degree proportionate to the privations they had endured. In Ireland accordingly, at least during the present century, as the condition of the poor has been decidedly worse than either in England or Scotland, so contagious fever has never ceased to be more generally prevalent. The same observation applies to the epidemic fever in London after the scarcity of 1800, (the last great epidemic which has occurred there) to the great continental fever of 1813-14, which followed the track of the French army retreating from Russia, but never made much progress in the victorious allied army; to the epidemic fever of 1817 in Italy, consequent on the scarce year of 1816; to the epidemic which affected the British army in Holland, after the disastrous retreat from Flanders in 1794; in Portugal, after that from Bruges in 1812; and to that which nearly decimated the British Legion at Vittoria in 1836."

[To be continued.]

FEMORAL HERNIA IN THE MALE.

To the Editor of the Medical Gazette.

SIR,

IF you think the following case and remarks sufficiently interesting for publication in your excellent periodical, I shall feel obliged by their insertion.

I am, sir,

Your obedient servant,

T. C. BUCHANAN.

Gloucester, March 31, 1841.

Thomas Price, labourer, æt. 65, who had been under my care a short time previously for an injury of the eye, was admitted into the Gloucester Infirmary on the evening of April 19th, 1840. He stated that during a fit of coughing, on the 17th, a swelling took place suddenly in his left groin; that vomiting immediately followed, and had continued at intervals ever since; that he had suffered a great deal of pain in the

bowels, but had not been able to procure any evacuation from them. On examination, a small enterocele was perceptible in the left groin, but it was difficult to determine whether its neck was above or below Poupart's ligament, on account of the margin of that ligament being very imperfectly defined. The parts in the groin were not so lax as they usually are; and although the neck of the tumor appeared to be situated deeper than in a case of inguinal hernia, and rather to the outside of the spinous process of the os pubis, yet manual examination did not entirely relieve my mind from doubt as to whether the hernia emerged from the abdomen above or below Poupart's ligament; whether, in short, it was inguinal or femoral. The abdomen was tympanitic, and painful on pressure; vomiting occurred occasionally. The pulse was 80, and easily compressible. After waiting for about two hours for the application of cold to the tumor, the administration of a purgative enema, the passing of the œsophagus tube, and the employment of the taxis, which was tried unsuccessfully, it was deemed expedient to perform the operation, as the tension of the tumor, and of the surrounding parts, precluded the probability of returning the hernia without it. An oblique incision was made over the tumor, and an enlarged gland situated in front of it was divided; the dissection was then proceeded with, and the sac, which did not contain any fluid, was cautiously opened. The intestine was then clearly found to emerge from the femoral ring; and the stricture, which was tight, and situated in the front part of it, was divided upwards by a probe-pointed bistoury passed along the groove of a director. The intestine, of a deep chocolate colour, was easily returned into the abdomen; and two sutures, with plaster, were employed to close the wound.

April 20th, 11 A.M.—Has not slept: no vomiting, but the bowels have not been opened; abdomen tense and tender; pulse 80, and compressible; tongue white.

Appl. Hirud. xvij. abdom. Sumat Hydr. Chlor. gr. iij. statim. R Magn. Sulph. ʒj.; Aq. Menth. Pip. ʒviiij. S. ʒj. omni horâ. Tea and arrow root.

10 P.M.—Bowels have been opened once freely, but he has since vomited; 698.—XXVIII.

abdomen rather less tender on pressure; tongue loaded with a whitish fur; pulse 84, and compressible; cough troublesome.

Omittr. Mist. S. Hydr. Chlor. et Ext. Hyos. aa. gr. ij. ʒiis horis. Potus abdom.

21st, 11 A.M.—Has slept at intervals, altogether about two hours; has vomited twice, and now feels sick; abdomen rather less tense and tender; about two hours since has had a purgative enema, which has not yet returned; pulse 80.

Rep. Pil.

10 P.M.—Has been so sick as to refuse taking the pills, of which he has only had three; bowels have been opened, but not freely; pulse 80; tongue furred; abdomen rather less tender, but quite as tense; he still feels sick, but wishes for a little broth, which was allowed him.

Rep. Pil. addit. Ext. Coloc. C. gr. ij. cuicque. The wound was dressed in the morning, and looked well.

22d, 2 P.M.—Has slept a little in the night, and this morning a purgative injection was given, which produced a pretty copious evacuation: he was sick in the night, and has just now vomited. Abdomen slightly tender, but still tense and tympanitic; pulse 78, rather full; tongue furred; cough distresses him.

Appl. Empl. Lyttæ Epigast. Rep. Pil. addit. Aloes, gr. j. cuicque dosi. To have an injection in the evening if the bowels are not previously opened.

10 P.M.—Has had an injection, and the bowels have acted pretty freely; the vomiting has ceased; he has taken a pint and a half of broth during the day, and has slept an hour at a time; feels better; pulse 84.

To take one pill in the night. Cont. Potus.

23d, 11 A.M.—Bowels have been twice freely opened in the night; abdomen soft, and not tender to the touch; pulse 72; tongue moist; feels comfortable. He appears to be now going on well, after having taken

Hydr. Chlor. gr. xxvij.; Ext. Hyos. gtt. xxiv.; Ext. Coloc. c. gtt. xvj. et Aloes, gtt. iv.

He was discharged, May 21st, quite well from the hernia, but still troubled with his cough.

REMARKS.—Although, in the pre-

ceding case, it was difficult to decide positively, by manual examination, whether the hernia was or was not femoral, yet I should have felt less hesitation in doing so, if the belief of the rarity of femoral hernia in men had not been so strongly impressed on my mind: more so than the observation of our great authority, the late Sir A. Cooper, warrants. I perceive, indeed, from the last GAZETTE, that Professor Cooper apprehends that crural hernia in the male is more frequent than the illustrious Scarpa supposed: and as a knowledge of its comparative frequency, with the more usual form, may prove of some utility in practice, and can only be acquired by extensive experience, I was glad to find the Professor's attention had been directed to the subject.

It may seem strange that aloes was given to the patient, but as the tympanitic state of the bowels at the time of its exhibition appeared to me to arise more from atony than inflammation, as we sometimes see in cases of colic, I did not think aloes inadmissible.

ON HIP DISEASE AND LUMBAR ABSCESS.

By WM. OLIVER CHALK, ESQ.

Resident Surgeon to the Royal Sea-Bathing Infirmary, Margate.

THERE is another circumstance attendant on the position of the limb in psoas abscess which tends greatly to obscure the diagnosis, especially when the first stage is somewhat advanced: it is the unusual prominence of the great trochanter, produced by crossing the limb affected over on the sound one. This appearance so much resembles disease of the articulation*, that it is often extremely difficult to form a right judgment; yet, generally speaking, this projection of the trochanter may be observed long before the matter quits the pelvis, and the absence of pain on percussion over the articulation will form the best means of distinction. It is, however, absolutely necessary to satisfy ourselves, if possible, on the point, since it involves a question of practice; for

if there be consecutive disease of the joint, the patient (independently of any other consideration) must not be permitted to move about as freely, as if the psoas muscle only were affected. These consecutive affections of the articulation are commonly fatal, especially among children—a fact which cannot excite our surprise, when we consider the extent of structure involved, the great destruction of parts that ensues, and the desperate severity of the local and constitutional symptoms. I do not remember to have seen a single instance of recovery under these circumstances. The case of M. A. Upton, æt. 6½, now under treatment, is one in which disease of the articulation exists, in conjunction with lumbar abscess, and seems to all appearance as if it would ultimately do well. The affection of the articulation, however, cannot be considered as consecutive in this instance, as it arose from a fall, whilst the former disease was only in its incipient stage. The following is the history of the case:—In the autumn of 1838, she suffered from a severe attack of scarlet fever: soon after her recovery she was observed to stoop, particularly when walking. January 6th, 1840, she began to complain of pain in the knee, which came on at night, and was always worse in the recumbent posture; she lay with the thigh flexed on the pelvis, and rested the limb affected on the sound one. Whenever any one attempted to move her, she screamed with pain. At this period surgical advice was obtained. Leeches, blisters, and an issue, were applied in the vicinity of the articulation; she was not allowed to move about; a suitable medical treatment was adopted; and, after a time, an amelioration of the symptoms ensued. She was admitted, as an in-door patient, May 14th. She did not then complain of pain in the hip or knee; nor was there any on flexion; but it was produced by extension, and rotation outwards, in the latter articulation. She limped very much; her health was delicate; she complained of pain on pressure in epigastrio; the pulse was quickened, and she suffered under febrile accessions; tongue furred; alvine excretions unhealthy. The hepatic treatment was pursued, and her general health soon improved. As she did not walk any

* The manner in which partial or complete dislocation of the head of the femur takes place from position has already been described in the cases of J. G. Butter and W. H. Elsworthy, at page 26 of the *Med. Gaz.* March 26th.

better, a pair of crutches was ordered. From this time she went on remarkably well, and, from having been a spare delicate child, had become strong and healthy, and had gained flesh. She suffered no pain, and seemed to be rapidly recovering. In the month of August, she unfortunately slipped whilst walking on her crutches, and in falling struck the hip and knee; from this time (although suitable remedial means were adopted) she began to experience severe pain in both articulations, flexion, extension, rotation, &c. considerably increasing it; she was entirely confined to her bed, and no apparent amelioration in her symptoms took place up to the period of her departure, October 6th. I saw her again in the November following. She was then suffering from hectic fever and constant cough, with profuse muco-purulent expectoration. The hip-joint was acutely sensitive; the slightest percussion over the trochanter caused excessive pain, as did any attempt at movement; there was a hard circumscribed fulness of the nates. Three leeches were applied to the epigastrium, and a bread and water poultice for an hour, to promote the bleeding. Aperi-ents of calomel and jalap were given once or twice a week, together with occasional enemata of warm water. To alleviate the cough, which was very troublesome, I prescribed the following mixture:—

R. Creasoti, ℥xvj.†; Tinct. Card. Co. ʒiij.; Essen. Pap. Alb. ʒj.; Sacchar. Alb. ʒij.; Aquæ Destillatæ, ʒviiss. Mfr. Mist. sum. cochl. duo ampla ter quotidie aut urgenti tusse.

I am induced to give the formula, as I have frequently found it of essential service in allaying the cough of patients in the latter stage of phthisis as well as in hooping-cough. A lotion, consisting of Iodine, two grains, and four grains of Iodide of Potass, dissolved in a pint of distilled water, was constantly applied to the articulation. In the course of a fortnight or three weeks the hectic symptoms disappeared, the hip became less painful, the cough entirely sub-

sided, and it has not since returned. As soon as the hectic fever was subdued she took Decoct. Cinchonæ, ʒiss. three times daily; whenever the constitutional effects of iodine became at all apparent, the lotion was discontinued for a short period.

I have just now examined her (April 9th): she is able, and has been for three weeks past, to move about on crutches; the limb is shortened, the toe scarcely touches the ground when in the erect posture; the circumscribed hardness of the nates has increased: she complains of pain on flexion and percussion. Her general health is greatly improved.

It occasionally happens that lumbar abscess forms on both sides of the spine; under these circumstances the patient's suffering is extreme, and the disease is commonly fatal. I can only call to mind a single instance to the contrary; it was the case of John Dimblebee, admitted in the seasons of 1828-29. The spine was not affected; the complaint had existed for several years, and, although there was considerable contraction about the hip and knee-joints, his recovery was complete. I saw him two years afterwards in perfect health, and scarce any trace of the disease existed. In the case of Jane Barnes, admitted May 12th, 1836 (where the complaint terminated fatally after she left the infirmary), the deformity produced by the exit of matter in the vicinity of both articulations of the hip, was indescribable, and her sufferings intense. As the exciting causes of psoas abscess differ in no respect from those of hip disease,* it will be unnecessary to enumerate them here. The general treatment is likewise the same, and need not be repeated.

I will, however, take this opportunity of adverting to a point of great practical utility, namely the necessity of relieving the lower intestines by enemata, as the peculiarity of the local disease renders the patient liable to suffer whenever accumulations take place in the colon. The presence of scybala is often productive of severe pain—a circumstance which is readily accounted for in the relative situation of the psoas muscle and colon, and one that should be carefully borne in mind throughout the whole course of the disorder. The fol-

† To form this mixture the Creasote should be mixed with Tr. Cardam. Co. and Sacch. Alb.; the distilled water should be added by degrees, and repeatedly shaken until a clear mixture is formed. The quantity of creasote may be increased if necessary.

The Essen. Papav. Alb. is a sort of fluid extract prepared by Messrs. Westwood, of No 16, Newgate-street.

* Vide Medical Gazette, March 26, p. 28.

lowing case is highly interesting, and shows the necessity of attention (if proof were wanting) to this particular point.

John Cliver, *act.* thirty-three, admitted May 9th, 1839, suffering under psoas abscess on the right side (which had found an exit in the groin), consequent on a kick from a cow about nine months previous: he was a shepherd. The discharge was rather copious, and of an unhealthy character: his general health was greatly impaired: he was labouring under hepatitis. The bowels were co-tive: he complained of great thirst: the skin was hot, and his pulse accelerated. He had great pain between the shoulders, and suffered acutely from pressure in epigastrio. He had frequent palpitations of the heart: the abdominal aorta was observed to pulsate violently at times. He occasionally complained of pain in both iliac regions, especially in the right: whenever this was the case, the discharge from the abscess increased, and the bowels were more inactive. Upon observing this I constantly relieved the symptom by aperients, or enemata. It is unnecessary to follow out the treatment, which extended over a period of upwards of four months, at the termination of which the abscess had nearly healed, but had formed another small opening, just above the anterior superior spinous process of the ilium: the discharge was very slight. He had so far recovered his general health and strength as to be able to walk with a crutch and stick, and was about to return home. On Sept. 25th he was seized with violent spasm at 11 o'clock in the morning. Antispasmodics were administered. Hot bottles of water were applied to the feet and pit of the stomach: hot brandy and water was given at intervals. The patient was greatly alarmed, and frequently expressed his conviction that if the pain continued he should die. The spasms soon subsided under this treatment, and he experienced no return of them until 3 o'clock p.m., when I was called to see him. He was suffering extreme agony: his countenance was exceedingly pallid: the surface of the body was covered by a profuse and cold perspiration: his breathing was accelerated: the pulse rather full and quickened: he repeatedly asserted that the pain was too

great to bear, and that he should die. I endeavoured to encourage him, and ordered a repetition of the remedies above described. I left his bedside for the purpose of procuring him a draught; but although three minutes could not have elapsed from the time of my absence until my return, he expired during the interval. A post-mortem examination was made 23 hours after death; every viscus of the body was carefully examined, and found in a healthy state, with the exception of the liver, which was engorged, and presented in some places a slight nutmeg appearance. There was an abscess occupying the right psoas muscle, which descending had formed an orifice just above Poupart's ligament, and another near to the anterior superior spinous process of the ilium: the sac was nearly obliterated, and the walls of the abscess were semi-cartilaginous, and several lines in thickness. The caput coli was very closely adherent to the upper surface of the sac by strong adhesions. It was at this point that accumulation had constantly occurred during life.

In lumbar abscess it is of the greatest importance to recognise the incipient symptoms, for if the disease be independent of vertebral caries, or unconnected (as is often the case) with any organic changes of the liver or respiratory organs, we shall generally prove successful in relieving them, or at least in modifying and restraining the suppurative process: and if we cannot altogether arrest the disease, it may be rendered far less formidable by a careful adoption of the constitutional treatment already described. Provided the pain be not excessive, the patient should be made to walk on crutches as early as possible: great care and attention being paid to have these of a proper length*, (as in *morbus coxae*); thus avoiding the contraction which commonly takes place about the articulations of the hip and knee, upon which the shortening of the limb in these cases depends. It is the opinion of many of our most able and experienced surgeons, that when vertebral caries exists, the patient should be confined to the recumbent posture on a bed or couch†. I cannot say that I ever

* The patients themselves, particularly children, if left to their own choice, will almost always select crutches which are too short.

† The prone couch has been used of late years,

found the practice successful, and it seems to me open to the following objections:—

1st. The mischief to the general health from want of exercise.

2dly. The loss of muscular power, which is always great under such circumstances.

3dly. The limb (in spite of every effort to the contrary) acquires a bad position, and, as we have already seen, the pain is always more urgent in the recumbent posture.

It has been asserted by those who advocate the system of rest in scrofulous caries of the spinal column, that by allowing the patient to move about in the erect position, the superincumbent weight of the body is hurtful; that the caries is increased by it, and the reparative process retarded. This mode of reasoning, however, seems to me fallacious. I think that too much importance has been assigned to the effect of superincumbent weight: for it may reasonably be asked of what use are the muscles unless to support the spine and to retain it in its natural position, and by their influence to sustain the weight of the body, as well as to minister to the locomotive functions. So long as the strumous diathesis remains unremedied, the reparative organs will be wanting: this must be at once apparent, if we admit that an impaired state of the nutritive functions (of which there can be no doubt) is essential to the formation of scrofulous habit: and, therefore, that whatever tends to alleviate it will best secure the well-doing of the local malady; but whether or not the argument be correct, long experience has taught me that provided the general symptoms be combated successfully, amelioration of the local mischief will most certainly follow. This circumstance should never be overlooked or forgotten in entering on the use of topical remedies.

The only objection that can be made, in my opinion, to allowing the patients to move about during the earlier stage, is the uncertainty of gait that accompanies it, especially among children, which renders them liable to falls, and consequently to an aggravation of the disorder; this, however, is in a great

measure remedied by the use of crutches. The exercise thus obtained is so beneficial to the general health and position of the limb, that it amply compensates for the risk incurred.

The case of Mary A. Heard, *act.* 28, admitted July 13th, 1836, suffering under incipient lumbar abscess, is a good illustration of the benefit derived from crutches, as regards the position of the limb: even under unfavourable circumstances. The case had been treated as an affection of the hip. The articulations of the hip and knee were greatly contracted. This state was rendered more permanent by a high shoe which she had worn for some time. She complained of pain in the hip and knee, particularly at night. She had great tenderness in the region of the liver. The digestive functions were much deranged. These symptoms were accompanied by a teasing cough.

I reported the case to Dr. Dennison, under whose care she was admitted, and with his concurrence she was placed under the hepatic treatment. The high shoe was removed, and she was ordered to walk on crutches. She underwent a course of warm bathing, &c. and by Sept. 3d was discharged cured, having entirely recovered the use of the limb.

The use of counter-irritants, such as moxa issues, &c. at any period of the disease, is open to the same objection as in morbus coxae: they are only so many means of aggravating the patient's suffering. I had an opportunity last summer of seeing a youth of 19 years of age who was suffering under lumbar abscess in its suppurative stage, and which had found exit at the side of the spine: the discharge was profuse. On the opposite side was placed a deep issue about two inches in length, which was in a state of great irritation. He was in the last stage of phthisis. Could any reasonable hope be entertained from such treatment, and under such circumstances? Yet such cases are of constant occurrence. The warm salt-water and douche baths will be found useful during the incipient symptoms: the latter should not be used if there be great pain. When once the abscess has made its exit from the pelvis, and begins to form on the inner side of the thigh, or beneath the gluteal muscles, our attention should be more than ever directed to the care of the patient's

and I am informed in some instances with benefit to the disease; but, from cases that have come under my observation, it has not only been of no use, but exceedingly prejudicial.

general health. The ioduretted lotions applied over the tumor will now be of use, especially if there be any heat of the parts. The ointments of iodine and iodine of potass, and iodide of mercury also, form excellent applications: but they must not be used too freely: by these means we may be enabled to moderate the secretion of pus, and secure a more rapid recovery when the abscess opens. I have remarked elsewhere that early opening of the abscess is prejudicial; and that it is always advisable to allow it to break of itself. This rule applies especially to accumulations of pus in the psoas muscle. I have sometimes had occasion to observe that, when the sac has been large, the quantity of matter secreted has varied according to the state of the patient's general health. If any circumstance tended to derange this, an increase was generally perceptible; but when it was remedied, an obvious diminution in quantity took place. I was for some time inclined to believe myself in error in this respect, but repeated and careful observation has assured me of the fact. The following cases shew to what extent pus may be secreted and reabsorbed, under careful attention to the general health.

Jane Redding, æt. 17, admitted Aug. 30, 1837, suffering from psoas abscess on the right side, and an ulcerated state of the foot, with caries of one of the phalanges. The accumulation of pus was enormous, and occupied the inner part of the thigh, which was nearly as large round as her body; the sac could not contain much less (upon a moderate calculation) than a gallon. She complained of pain in the hip and knee, and suffered severely when she attempted to move about. She was labouring under hectic symptoms. The usual treatment was adopted. She left October 16th. Her general health was greatly improved, and the abscess considerably diminished in size. She returned to the infirmary May 18, 1838; her general health had continued good during the winter; the sac had decreased, and the foot was healed. She returned home October 16, in excellent health: the abscess now formed a circumscribed tumor of some size at the upper and inner side of the thigh, which seemed as if it would be ultimately absorbed.

Thomas Brenchly, æt. 23, admitted

May 19 1839, suffering from posterior curvature of the spine, with consequent psoas abscess, which had descended beneath Poupart's ligament on the inner side of the right thigh, forming a large tumor. He complained of great tenderness on pressure in the epigastrium; the skin was yellow, and the conjunctiva of either eye suffused with bile: the local affection originated in a sprain four years previous. The hepatic treatment was adopted, and by the time he left the infirmary, October 9th, the tumor had entirely disappeared, and I could not, by the most careful examination, detect the slightest fluctuation. His general health had undergone great improvement.

Thomas Whitehead, æt. 24, admitted May 13th, 1840, suffering from an accumulation of matter on the upper and inner side of the left thigh consequent on psoas abscess. He had been thus affected eighteen months. Fluctuation was very perceptible low down on the inner side of the thigh: his general health was not much impaired. He left the infirmary October 23d, greatly improved in every respect. The accumulation was scarcely observable at the time of his departure.

W. O., æt. 8, admitted as an out-door patient May 22d, 1840, labouring under psoas abscess in its incipient stage. He complained of great pain in the hip and knee, which was worse at night. He was suffering from hepatic congestion; the tongue was furred, pulse quick and small, alvine excretions irregular. Not long after his arrival I observed a fulness on the upper and inner side of the right thigh, which soon increased, and proved to be an accumulation of pus. The pelvis was much canted up, and thus gave a greater appearance of lengthening to the limb than usual. The usual plan of treatment was followed, and he left the infirmary October 23d, greatly improved in his health. The abscess had been entirely absorbed. I have twice had an opportunity of seeing him during the winter, and he remains quite well. Other cases might be related bearing on this point, but it appears to me that the foregoing are sufficiently demonstrative of the inexpediency of early opening; for if nature will promote a cure, it is far better than the employment of artificial means; whether matter be liberated from a chronic abscess of a large size

by incision, or an outlet form of itself, it should never be forgotten that this is always fraught with more or less risk to the patient. In the latter instance, however, there is assuredly less than in the former. Provided we continue our attention to the general health, the longer the abscess is in forming an exit, the more probability will there be (generally speaking) of a happy result.

[To be concluded in our next.]

CLEFT PALATE.

To the Editor of the Medical Gazette.

SIR,

I TAKE the liberty of sending you an account of a case of cleft palate, in which an operation was performed, with as much success as could have been anticipated, when the large size of the interval between the edges of the tissue be taken into consideration. The brief narration of such cases is not unattended with advantage, and the means of dissemination of the result of experience in the treatment of many of the ordinary forms of surgical disease, through such publications as your own, lead one to record individual examples of success, and which cannot well be detailed and given to the public in any other manner.

A little boy, 15 years of age, was born with the defect alluded to, accompanied with hare-lip; the palatine processes of the superior maxillary and palate

bones of the left side being also deficient, nearly as far forwards as the alveolar process. The ordinary operation for hare-lip was performed at the London Hospital during infancy.

I was induced, at the request of the parents, to make a farther effort to rectify an evil so detrimental to him, from his consequent defective pronunciation.

The ordinary steps of the operation differ but slightly from those frequently adopted; but a slight detail of them may not be uninteresting. The extremity of each half of the uvula was successively seized with Asseldini's forceps, and with a spear-pointed knife a slice of the edge of each half of the fissured soft palate removed. The instrument next employed was one of extreme simplicity, and which answered perfectly. It consisted of a simple silver style, of about three inches in length, fixed firmly in an ebony handle, and bent at its extremity to the curve represented in the drawing: at the end of this, a steel point, with an eye capable of holding a moderate-sized ligature, is affixed. The advantage of its being made of silver is, that it is capable of being bent to any curve, to suit the necessities of the case. There was no difficulty whatever in passing the end of the instrument, armed with the ligature, through the right flap of the velum, the point of the instrument being carried from behind forwards, so as to be seen projecting into the mouth, and with a long pair of elastic forceps the ligature was laid hold of on the *concave* side of the needle, and drawn forwards: the instrument was then withdrawn, the

ligature of course being still held in its eye, and was then turned to the opposite side, and made to traverse in the same manner—namely, from behind forwards—the left flap. The object was now to disengage the ligature completely from the needle, which could only be done by seizing it on the *convex* side; a point of no great difficulty to accomplish. The needle was then entirely withdrawn. As many ligatures as the surgeon thinks

fit may in this manner be employed. In the case now under consideration, three, which is the usual number, were used; and the parts were brought together by the indices fingers. As there was considerable stretching of the soft palate, from the immense size of the aperture, a longitudinal incision was made on each side through the palate, after the method advised by Dieffenbach, and the tension was thereby most materially diminished.

The union was exceedingly good, but not quite perfect.

An artificial palate can, I have no doubt, now be worn: but it is found necessary to attach this to the teeth; and as the canine teeth are gradually descending, Mr. Craigie, into whose hands he has now fallen, is waiting until they are so far advanced as to become fixed objects for its attachment.

The only difficulty, and that is one of a comparatively trifling nature, which can occur in the employment of the needle, arises from the needle, after being withdrawn through the second flap, being found still implicated in the ligature; and all that is requisite to rectify this error is, either to remove the ligature on one side, and re-introduce it, or to draw it through the mouth, cut out the needle, and tie a knot in the ligature, which will, on the securing of the ligature, be found afterwards readily drop out when, after adhesion had taken place, the anterior knot was cut away. This accident occurred in the introduction of one of the ligatures, but occasioned no inconvenience.—I am, sir,

Your obedient servant,

JOHN ADAMS.

April 1841.

REMARKS ON MR. T. B. CURLING'S
NEW METHOD OF
CURING PARALYTIC PTOSIS BY
OPERATION.

To the Editor of the Medical Gazette.

SIR,

IN your journal of the 26th instant, Mr. Curling has favoured the profession with the details of an operation successfully performed for the cure of paralytic ptosis. A somewhat similar operation, he informs us, was undertaken by Mr. Hunt, of Manchester, in a case of traumatic ptosis of one lid consequent upon a division or laceration of the levator palpebræ muscle; and he seems to consider it equally applicable to the one form of the affection as the other. The subject of the operation, in Mr. Curling's case, was a gentleman affected with double ptosis and divergent strabismus from palsy of the muscles supplied by the third

pair of nerves; and his condition, which is so well described by Mr. Curling, was such as fully to warrant the interference of a surgeon. But, sir, in admitting the propriety of operating on one eye-lid when both are affected, is a surgeon justified in having recourse to the operation when one only is paralyzed?—a case of far more frequent occurrence. I think not. When palsy affects the muscles supplied by the third pair of nerves, the iris also participates in the same condition, and the pupil is dilated; and where the paralysis is as complete as in the case described by Mr. Curling, largely dilated, and incapable of extraction under the strongest stimulus of light, I have ever regarded this conjunction of the dilated pupil, with palsy of the upper lid, as a most admirable and provident contrivance for the protection of the retina. Had the orbicularis palpebræ, instead of the levator palpebræ, received its nervous influence from the same source as the iris and the three recti muscles, what would have been the condition of a patient in whom these parts were paralysed?—unable to close the lids or to roll the eye under them, (a movement which, in part, supplies the defect of the patent state of the eye-lids in cases of paralysis of the portio dura) the pupil dilated, immobile, and incapable of excluding a too great abundance or intensity of light: either corneitis, with its attendant consequences, ulceration or sloughing of the tonic, and escape of the humours, would have resulted, or retinitis, terminating in total blindness, must have ensued. It behoves us therefore, in recommending an operation for the alleviation of present distress, not to lose sight of probable ulterior consequences, and to be careful that, in having recourse to analogy as our guide, we do not overlook those apparently minor circumstances in which the analogy does not hold, but which must be taken into account, before we can confidently predict, or rationally hope for, success. These remarks are not made in a spirit of criticism, but are intended rather as a caution to those more zealous than discreet members of our profession, who, in their eager scramble for cases to operate on, pay too little regard to their own inexperience or their patients' welfare. Fortunately cases of paralytic ptosis are much more

rare than those of squinting and strabismus, but should some unfortunate victim of this disease fall into the hands of an inexperienced operator, and too large a portion of the upper lid be excised, either ectropium would be produced, or the remaining portion of the lid might be not sufficient to cover the eyeball, unless by strong contraction of the orbicularis palpebræ. In either case the probable result would be corneitis and its consequences, from inability of the muscles to roll the eye under the upper lid; or retinitis, from inability of the pupil to contract and exclude too great a degree of light.

I am, sir,

Your obedient servant,

C. HOLTHOUSE,

Surgeon to the St. Pancras General Dispensary.

13, Keppel Street, Russell Square,
March 31, 1841.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

IMPROVEMENT OF MADHOUSES.

THE division of labour has often been panegyricized by political economists; and it is observed by Adam Smith that the number of hands employed in the making a pin, contribute not only to the excellence but to the quickness of the work. In fact, by this parcelling out of the manufacture among many artificers, more and better pins are made, than if each man attempted to make entire pins. Just so in the reform of church and state, the business is undertaken with the greatest vigour by those who confine themselves to one branch of the subject; who, as it were, keep for ever at the head of the pin, careless of the silvering or pointing. Dr. Caleb Crowther, on whose opinions we commented a few years ago*, appears to be one of

these reformers, who are chiefly occupied by a single topic; and though it must be confessed that his zeal sometimes outruns his discretion, yet few can read his censures without deriving some useful hints from the perusal. Dr. Crowther, indeed, as we showed in our former article, is one of the angriest of critics. He reminds one of the description of that fierce satirist, whose pen was like a drawn sword, and whose invectives produced the most violent emotions of terror in the breasts of those who were conscious that they had deserved them*.

Like every eager reformer, he not only shows with much vehemence that things are wrong, but is satisfied that he could set them all quite right; whereas, though it is tolerably easy to point out the incongruity and incoherence of all human systems, we doubt if even Caleb Crowther himself could substitute perfection in their stead. Nothing is more easy, for example, than to show, as he did in his former essay, that there are defects in the present method of electing the medical directors of asylums. But, as we then answered, there are obvious objections to the plan proposed by Dr. Crowther, of appointing them by a Minister of Health, assisted by a medical board. Elect them, if you please, by the votes of five hundred governors, or by a medical jury and a *concours*, and objections—good sound objections—will not be wanting. Moreover, without believing, as Dr. Crowther does, that the most ignorant men will often produce the best testimonials, we can easily understand that the man who is theoretically the most fit, may not, in vul-

* *Ense velut stricto quoties Lucilius ardens
Infremuit, rubet auditor, cui frigida mens est
Criminibus, tacitâ sudant præcordia culpa.*

When angry Crowther, as with flaming sword,
Rages, his hearers dread each bitter word;
Recorded crime the guilty heart affrights,
And sad mad-doctors tremble as he writes.

gar phrase, *work* the establishment the best.

Again, in his present essay*, he declaims against the luxuriousness of directors of asylums, and sees much mischief in their dinner-parties. A feast of three courses occupies the servants of the institution, and detains them from their regular offices; and on one occasion a director "on hospitable thoughts intent," when summoned to a maniacal patient, did not go to see him till he had broken two hundred and thirty-six squares of glass. It is quite clear that it is arithmetically and morally possible to make a director so rich that he shall be too great a man for his place; whether this has ever been done, and especially whether it is the case at the West Riding Asylum, on which Dr. Crowther's heaviest censures are showered, we know not. We should be glad to hear what his salary is. A well-paid medical officer in any public institution is so singular an exception, that the whole of this rare class existing in England might be counted on one's fingers; and to hear of such an instance is as refreshing as to see a warm colour after long gazing on cold tints. But though it would be easy enough to avoid this pleasant fault, and give the resident officer of an asylum a salary of sufficient scantiness, in any degree from the bare subsistence of an assistant-surgeon in the army, down to the pretext of pay bestowed on a Union officer, or the avowed nothing given to a dispensary doctor, yet this frugal plan has its disadvantages, and is as unjust to the patients as it is to the physician. Instead of procuring the cheerful services of a man of talent, who felt that he had at length obtained something like a reward for the labours of a life-time,

we should be liable to a continual alternation of the dull and the disappointed; the former unable, and the latter hardly willing, to perform the duties of their office efficiently. When a medical place is accepted with little pleasure, and vacated with great alacrity, *delirant reges, plectuntur Achivi*—it is the rulers of the institution who err, but the poor patients who suffer.

Again, the Director of the West Riding Asylum, according to Dr. Crowther, makes presents of the produce of the garden to his friends, and this is forbidden by the printed rules of the Institution, though perhaps countenanced by the tacit permission of the visiting magistrates. The rules also say, that "any officer or servant found making a perquisite of any kind whatever, will be instantly dismissed." It certainly would seem desirable, either to alter the statutes, or make the practice agree with them; for as the rules direct the vegetables not consumed in the Asylum to be sold for its benefit, each cucumber presented to the neighbours is a loss, though a small one. It might be said, indeed, that the question was, whether these infractions of the law were so frequent as to render it advisable for the authorities to interfere; or whether they were so rare and minute as to make interference inexpedient, and almost ludicrous; while to this it might be answered, that perquisites, like fame, are *parva metu primo*, but often rise to great heights from modest beginnings. So that it is one of those practical questions of constant recurrence, where the difficulty is to draw a line between small and great, and decide with mathematical exactness where the important begins. Who, for instance, would grudge a visitor to an hospital a dose of peppermint and rhubarb; yet who would allow him to be constantly supplied with medicine gratis; and who can shew where his

* Observations on the Management of Mad-houses. Part the Second. By Caleb Crowther, M.D. 1841.

demands began to be unreasonable? On the whole, however, we like adherence to the most rigorous scrupulosity, and cannot, therefore, but approve of Dr. Crowther, who, when physician to the institution, "declined accepting from the matron a present of fruit, produced in the garden belonging to the Asylum, because I conceived that she had no right to give, nor I to receive, public property."

Perhaps the neatest way of getting out of this scrape would be to allow the Director the disposal of the vegetables not consumed in the Asylum, as a sort of increase to his salary. Another accusation which Dr. Crowther brings against the Wakefield Asylum, is founded on a remarkable case; so remarkable, indeed, that the desire of communicating it to the public may possibly have been the chief motive for writing this second essay.

Susannah Roginson, having become deranged from disappointment in love, was admitted into the asylum on the 19th of January, 1828, at the age of twenty-three. On the 1st of April, 1836, a dead child was found in her bed, and on the 18th of the following month she died herself. Susannah Roginson had long been in a state of fatuity, and never left the ward. In the day-time she was confined in a chair by straps, and at night in her bed. She was insensible to the calls of nature, and, at the time of the discovery of the child, was greatly emaciated, and of disgusting personal appearance. Was this poor creature the mother of the child? Dr. Crowther is almost sure she was; we think it at least as likely that she was not, and that some other woman wished to conceal her frailty by laying its evidence in Susannah's bed. The visiting physician, says Dr. Crowther, was not made acquainted with the incident, while the nurses and servants were

pledged to secrecy; but the fact was communicated to some of the visiting justices. Instead of this, says Dr. Crowther, the director ought to have sent for one of the surgeons to the Asylum, who should have examined Susannah Roginson. So far, so good; but when he adds that if she had turned out not to be the mother, the matron and housekeeper ought to have examined all the nurses and female servants capable of bearing children, we must differ from him. Such an examination of a host of women on mere speculation, seems calculated to do any thing but effect Dr. Crowther's object of curbing indecency, and preventing the Asylum from becoming a scene of licentiousness. This examination can only be permissible when there are the strongest grounds for suspicion against the individual. This affair came to Dr. Crowther's ears about three years and a half after it had happened, on which he sent an account of it to the Secretary of State, and in due time received an answer stating that Lord Normanby did not "think it necessary to take any further proceedings on the subject."

After the receipt of this letter the visiting justices held an inquiry, which also terminated in nothing. The director stated to them, truly enough, "that such mischances could not at all times be prevented in an institution of this kind, by the utmost possible vigilance;" and the justices were probably influenced by the length of time which had elapsed since the incident.

The diet of the patients was changed for the worse, says the censor of Wakefield, by the substitution of boiled rice and onions for the regular Saturday's dinner of four ounces of coarse beef made into Irish stew. The excuse assigned was, that old potatoes cannot be procured at certain seasons of the year, and that the dish is not good

when made with new ones. Dr. Crowther does not think this a good reason, or the true one; however, the old Saturday's dinner has been restored.

As for the credibility of the servants of a madhouse, Dr. Crowther believes it easy to ascertain their moral character, and, consequently, the value of their evidence, through the medium of daily visitors. These last he thinks, and probably with truth, are a great check on the maladministration of hospitals and asylums. It is the business of a daily visitor to prevent fraud, waste, or neglect; to insure cleanliness; to examine all the provisions in the house, cooked or uncooked, and see that the patients get a proper quantity of good and wholesome food; and to notice the misconduct of officers or servants. If all the patients of a madhouse are sent to bed at six o'clock, owing to the absence of keeper, director, and matron, the unexpected visit of such an inspector will detect the negligence. Nay, his soothing converse contributes to the cure of the insane; for the patient often fancies that the nurse, director, and physician, are in a combination against him, and is tranquillized by the assurances of one who has no interest but in promoting his welfare.

Last August Dr. Crowther visited four of our great lunatic hospitals—Haslar, St. Luke's, Bethlem, and Hanwell. He was pleased with them all, but is enchanted with Hanwell.

In the improvement of lunatic asylums, Dr. Crowther is a useful co-operator; for though he is far too angry to be always in the right, he is far too clear-headed to be always in the wrong.

event at the School of Pharmacy in Paris, which cost M. Hervy his life. He was preparing some carbonic acid in its liquid form, in Thilorsen's apparatus, which is composed of two cylindrical reservoirs, of about the thickness of two centimetres, with an interior diameter of from eight to ten centimetres. Each of those cylinders had an interior space of about four litres. The carbonic acid was produced by the action of sulphuric acid on the bicarbonate of soda, which were introduced simultaneously into one of the cylinders. A communication was then established between this first cylinder and the other, and the carbonic acid passed into the second cylinder by distillation. In the first cylinder remained a residue, consisting of sulphate of soda, which was taken out to replace it by a new supply, in order to obtain a determinate quantity of the liquid carbonic acid: a quantity which, as we have seen, may be raised to four litres. The first cylinder is supported on two trunnions, which keep it in equilibrium, and allow an extensive degree of oscillation.

It was at the moment when M. Hervy was balancing the cylinder on the trunnions, to effect the mixture of the acid with the soda, that the explosion took place. At this moment there was no one near except M. Hervy and a friend who was assisting him. The latter was thrown down by the explosion, but was not struck by any fragment of the machinery. Not so M. Hervy. The apparatus was on the floor of the room, and the whole effect of the explosion was directed against his legs, which were cruelly mutilated, so as from the commencement to hold out little chance of saving his life. Amputation of one of the limbs was performed next day; and in three days more this unfortunate victim to science had ceased to exist.

The explosion was accompanied by a frightful noise, and considerable injury to the apartment. It is almost unnecessary to add, that this experiment will not again be attempted in connection with the public lectures*.

DEATH FROM AN EXPLOSION OF CARBONIC ACID.

THE daily journals have already made the public aware of the deplorable

SELECT SURGICAL CASES.*

Reported by GORDON BUCK, M.D.,

Surgeon of the New York Hospital.

Convulsions following an old injury of the head; cured by the application of the trephine†.

AUGUST 22d, 1839. In company with the above named gentleman, I visited Mrs. M'D., aged 35 years, a person in humble circumstances, who was then recovering from a severe attack of convulsions, for which it had been necessary to employ the most active depleting means. She was pale and feeble, but able to sit up, and had been confined for several weeks. Upon careful inquiry, the following particulars of her case were ascertained. Three years previous, while living in the city of New York, she received a blow in the middle of the forehead from a stone, which stunned her for a short time. On recovering her senses, vomiting came on, and continued for several hours. Two or three days after the injury, Dr. Mott saw her, and removed two small portions of bone. The wound continued to suppurate for several months afterwards, and then healed up. About eighteen months after the accident, she was attacked with convulsions, when far advanced in pregnancy with her third child. Bloodletting, with other depleting remedies, relieved her, so that she recovered her usual health, and went her full time. After a respite of several months she was attacked a second time, and relieved by the same means. She was now recovering from the third attack, which had been more violent and protracted than either of the preceding; during the interval that had elapsed between it and the second attack, she had several times suffered from threatening symptoms, such as flushed face, drowsiness, and torpor, of which she had been relieved by bloodletting. She never suffered from headache, nor referred any uneasy sensations to the seat of the wound. During the attacks, her face and all her limbs were alike convulsed. She was evidently agitated by our visit, and her recollection confused; with the assistance of her husband, however, she was able to make out the order of different occurrences. The cicatrix upon her forehead presented the following appearances: it was an inch and a half in length, in the form of a narrow furrow, with its upper half lying in the median line, and its lower a

little to the left of it, and terminating at the eyebrow; it was one-third of an inch in width, one-fourth in depth at its upper half, growing more shallow towards its lower extremity; there was evidently a loss of a portion of the external table of the skull, and the cicatrix of the skin was closely adherent to the bottom of the furrow. The parts were free from tenderness or pain. The patient, as well as her husband, was exceedingly anxious for relief, and willing any operation should be performed that afforded a prospect of benefit.

Our opinion concurring in favour of trephining, Dr. Fuller proceeded to perform the operation. A semi-lunar incision was made across the forehead, with its convexity directed downwards, intersecting the cicatrix near its inferior extremity, and extending an inch on either side of it. From the middle of this, a second incision, two inches in length, ascended along the median line: the angles were dissected up, and the periosteum detached from the bone. The first application of the trephine included about half an inch of the upper extremity of the furrow, and the disc removed appeared to be of unusual thickness, owing to increased deposit of osseous matter upon its inner surface. A second disc was removed, joining the first at its lower edge, and including the remainder of the furrow; the thickness of this disc exceeded that of the first, and was nearly half an inch. It was perforated by a foramen that transmitted a vein from the scalp to the sinus; the surface of the dura mater exposed was of a normal appearance. A moderate oozing of blood took place during the operation; but no ligatures were necessary. A single suture secured the angles of the wound in their proper situations, and the edges were kept in contact by adhesive straps. Compresses of lint, secured by long adhesive straps, completed the dressing. The patient, after the operation, expressed satisfaction at the relief it had afforded; her head, she said, felt altogether different from what it had before. The wound healed kindly by the first intention, and in about a fortnight she resumed her accustomed occupations.

AUGUST 31st, 1840. This patient has continued to enjoy good health, without any return of convulsions; though once or twice she has had some threatening indications, which Dr. Welch has relieved by seasonable treatment.

Fracture of the second lumbar vertebra, without paralysis.

This case, as well as the following, is interesting, from the circumstance that there was no paralysis, although fracture of the vertebra existed.

Daniel Wilson, born in Wales, aged about 37 years, of very intemperate habits, was

* From the New York Journal of Medicine and Surgery for October 1840.

† This case occurred in the practice of Dr. A. Welch, of Wethersfield, Connecticut, through whose courtesy I was invited to see it, and with whose approbation, as well as that of Dr. Fuller, of Hartford, who performed the operation, it is now made public.

admitted into the hospital in a state of delirium tremens, which continued several days, until twenty-four hours before death. Nothing could be ascertained respecting the nature of the injury he had received, nor was its extent suspected until he recovered his reason sufficiently to make it known himself, when it was ascertained that several days before his admission he had jumped from a garret window forty feet in height, in a fit of delirium. His right foot and ankle bore marks of contusion, and the extremity of the fibula was broken off. Before he regained his reason, it was impossible to keep him in bed; he was constantly going about the premises. After this, however, he began to complain of great pain, and soreness in moving his body, and as he lay in bed his head was thrown far back. On examining his back, the spinous process of the second lumbar vertebra presented an angular projection; pressure upon it gave no pain, nor did paralysis exist.

On dissection, blood was found extravasated between the folds of the mesentery and into the muscular and cellular tissue, covering the lumbar vertebrae. The body of the second vertebra was broken into fragments, the first and third were uninjured; the membranous sheath, as well as the enclosed cord, were sound.

Fracture of the skull, and of the second lumbar vertebra; without paralysis.

Q. D. was admitted, December 29th, 1839, into Ward No. 4, of the Marine Department. He had been knocked down in the evening by a carriage running against him. Several contusions of the scalp existed, besides a deep wound of an inch in length, in the axilla, from which there was but little hæmorrhage. The following morning, having recovered from intoxication, he complained chiefly of his back, and referred his pain to the lumbar vertebrae. There was no appearance of external injury or displacement; pressure did not much increase the pain. He was able to move in any direction, and even walked about the ward till the day he died; his face was flushed, and at times he was delirious. He was exceedingly averse to allow any thing to be done for him. At eleven o'clock, the third night after the injury, he was seized with a fit, and five hours after died.

Dissection.—There was a crack in the skull, running from the vertex on the left side to the foramen magnum. The whole surface of the right hemisphere of the cerebrum was covered with a layer of coagulated blood, thickest over the inferior surface of the middle lobe, where the convolutions were softened into a pultaceous mass. The veins of the pia mater upon both hemispheres were loaded with blood. The second lumbar

vertebra was fractured across its body. The anterior vertebral ligaments remained entire, excepting on the left side, where a small spicula of bone had obtruded. The cellular and muscular tissues around were infiltrated with extravasated blood.

APOTHECARIES' HALL, IRELAND.

MEDICAL REFORM.

To the Editor of the Medical Gazette.

SIR,

YOUR giving insertion to the enclosed in your valuable journal will oblige,

Your obedient servant,

GEORGE ATKINSON,
Secretary to the Court of Examiners of the
Apothecaries' Hall, Dublin.

April 8, 1841.

The Governors and Company of the Apothecaries' Hall of Ireland, coinciding in the opinion generally entertained that a change is required in the constitution of the medical profession in these kingdoms, have taken the subject into their consideration, in the hope of contributing to the removal of some of the difficulties with which it is surrounded, and of laying the foundation of an effectual and salutary reform.

The Governor and Company have been, for a long time, desirous of a general amendment of the laws which regulate medical affairs; but, in consequence of the divisions which have hitherto prevailed among the different presiding bodies, they despaired of effecting any arrangement which would have been commensurate with the wants of the profession as a whole, and had to restrict their attention to such changes as appeared to be called for in their own department. Their views on this subject are embodied in the draft of a bill which they are prepared to submit to the wisdom of the legislature, and, with regard to the nature of which, all that is necessary here to be stated is, that it is in conformity with the principles which they now wish to promulgate as the basis of a more general measure, the period having at length arrived when, through the concurrence of the different medical corporations, a full and comprehensive reform may be expected.

The Governor and Company, in delivering their opinions on so important a subject, wish to premise, that while they give a ready assent to the faulty constitution of the existing corporations, they entirely disbelieve they have operated injuriously upon the public, or that they are incapable of adaptation to the wants of the profession; they must express their regret, therefore, that any bill should have been introduced

into parliament having for its object the supersession or annihilation of these institutions, which, with all their alleged imperfections, have sedulously administered to the wants of the people, and provided well-educated practitioners in every department of the healing art; and it cannot be too much urged that the grievances complained of have reference principally to the well-being of the profession itself, and that the public are only interested in the changes sought, so far as they are calculated to engender a better spirit of co-operation and harmony in the medical community.

The Governor and Company, however, representing a numerical majority of the practitioners in Ireland, are not the less sensible of the magnitude of the interests at stake, or less disposed to aid in a consummation so greatly to be desired, but while professing to have the same objects in view, they must dissent from a large portion of their brethren who would seek for them in the establishment of a "one faculty of medicine," in place of the tripartite representation which has so long existed; convinced by long experience that excellence in the respective departments can only be attained by sectional separation, and that the appointment of different institutions to preside over the branches of Physic," "Surgery," and "Pharmacy," is founded in wisdom, and advantageous to the public.

The Governor and Company consider that the real grievances under which the profession labours, arise, in the first place, from the irresponsible constitution and unequal privileges of the corporate bodies; and in the second, from the want of uniformity of education and reciprocity of rights among the members of the respective departments in the three kingdoms.

The Governor and Company accordingly propose the following legislative changes:—

1.—A full extension of corporate rights and advantages to the licentiates belonging to each branch of the profession.

2.—The establishment of uniform curricula of study for England, Ireland, and Scotland.

3.—The institution of a "General Board of Superintendence and Control" in each kingdom—to be composed of an equal number of representatives from each branch of the profession, and to be elected annually by voting papers (as proposed by Mr. Warburton,) whose duty it should be to regulate education—to appoint Censors to attend on the different Boards of Examination—to grant licences for practice to (but not examine) those presenting diplomas from the different Corporations—to recognize teachers and schools—to keep and publish registries of the qualified, and to act in general as a Court of Appeal and Board of Health.

4.—"Diplomas in Medicine" to be granted only by Universities and Colleges of Physicians, "Diplomas in Surgery" by Colleges of Surgeons, and "Diplomas in Pharmacy" by the Apothecaries' Halls.

5.—A licence for "General Practice" to be granted in *future* only to candidates presenting the joint diplomas of the College of Surgeons and Apothecaries' Hall.

6.—A right to recover professional charges to be conferred on those holding the licence of the Board, and not upon others.

7.—Individuals holding the licence of the Board to be alone eligible to fill situations in the Army and Navy, and public institutions.

8.—The establishment of an Apothecaries' Hall in Edinburgh.

9.—The rights and privileges of existing practitioners to be saved in the most full and ample manner.

By order,

GEORGE ATKINSON, *Sec.*

Dublin, Mary Street, March 5, 1811.

ANCIENT USE OF FRENCH AT CAMBRIDGE.

MANY of the public forms of address used by the Bedells, as will be seen in subsequent parts of these extracts, were in the French language; some of them were probably derived, along with nearly all our other forms of proceeding, from the University of Paris, the most ancient and the most celebrated of the universities of Christendom. The use of the French language, which was that of the Court, was permitted, in common with Latin, in the statutes of some of our earlier colleges, such as Clare Hall, founded in 1326, and also in those of King's Hall, founded about the same period, as given by Richard II. Mr. Hallam has referred (Introduction to the Literature of Europe, p. 63), to a similar regulation in the statutes of Ariel College, Oxford, founded in 1328. No such permission was given in the more ancient statutes of Merton College, or in those of Peterhouse, which were almost entirely copied from them.—*Observations on the Statutes of the University of Cambridge.*

[In another part of the work Dr. Peacock corrects the statement as far as regards Peterhouse, where in the ancient statutes the scholars are requested to use "Latino eloquio nisi forsitan aliquotiens et ex justâ causâ et rationabili Gallico, sed perraro Anglico fruuntur," &c.

It is hardly necessary to observe that in early times, when Latin was the dialect of the learned, and French the language of the court, English must have been considered a rustic jargon, just good enough for a fair or market, like the Flemish or *Platt Deutsch* of the present day.]

NOTE ON PTOSIS.

To the Editor of the Medical Gazette.

SIR,

MR. HUNT's observations on my case of ptosis, which appeared in the last number of your journal, scarcely require any reply, the accuracy of my remarks not being called in question: for it does not appear the operation has ever been practised before in any case of paralytic ptosis. My object was to show, by experience, that the plan is equally applicable to the paralytic form of the affection as to that consequent on injury of the levator palpebrae muscle. I had not preserved any note of the journal in which Mr. Hunt's case was recorded, or I might have alluded more particularly to it, and noticed his recommendation of the operation in cases of paralytic ptosis. The objection to the operation, on the score of the paralysis of the third nerve affecting the iris, suggested by Mr. Hunt, did not apply to the case in which I operated, as the pupil acted, though sluggishly, and was not preternaturally dilated.—I am, sir,

Your obedient servant,

T. B. CURLING.

1. Mount Place, London Hospital,
April 13th, 1841.

UNIVERSITY OF LONDON,

SOMERSET HOUSE.

THE following gentlemen have been appointed Examiners for Medical Degrees for the ensuing year, commencing July 1st.

In Anatomy and Physiology.—T. Kiernan, Esq. F.R.S. and Professor Sharpey, M.D. F.R.S.

In Chemistry.—Professor Daniell, F.R.S.

In Botany.—Rev. Professor Henslow.

In Materia Medica and Pharmacy.—Dr. Pereira, F.R.S.

In Medicine.—Dr. Billing and Dr. Tweedie, F.R.S.

In Surgery.—Mr. Bacot and Sir Stephen Hammick.

In Physiology and Comparative Anatomy.—Dr. Roget, F.R.S.

In Midwifery.—Professor Ferguson, M.D.

In Forensic Medicine.—Professor Daniell, Dr. Ferguson, and Dr. Pereira.

SOCIETY FOR RELIEF OF WIDOWS
AND ORPHANS OF MEDICAL MEN

IN LONDON AND ITS VICINITY.

WE beg to direct the attention of our readers to the advertisement announcing that the Annual Dinner of this Society will take place to-morrow (Saturday), when H.R.H. the Duke of Cambridge has graciously consented to take the chair.

LECTURES
ON THE
PRINCIPLES AND PRACTICE OF
PHYSIC.

Delivered at King's College, London.

By DR. WATSON.

LECTURE XXXI.

Spinal hæmorrhage. Paraplegia. Facial palsy and facial anæsthesia: their symptoms, prognosis, and treatment. Other forms of local paralysis, and local anæsthesia.

I HAVE done with apoplexy as it respects the brain; which is the same thing as to say that I have done with apoplexy. You will find the same term applied, indeed, to effusions of blood in other organs of the body: but this use of the word is a perversion of language. Apoplexy, as I have frequently observed before, is the abolition of the functions proper to the *brain*; of sensation, voluntary motion, and thought. In short, it is coma, coming on under certain circumstances.

Spinal hæmorrhage.—I shall not speak therefore of *spinal apoplexy* (though that would be less improper than *pulmonary apoplexy*, or *hepatic apoplexy*), but of *spinal hæmorrhage*. Of this I really have little to say, except that it is well known occasionally to occur; and that the symptoms to which it gives rise are by no means peculiar or distinctive. They consist in *pain* in some part of the spine; *convulsions*; *palsy*: that is, they are the very same symptoms which inflammation, softening, mechanical violence, and other disorders of the same part, may give rise to. Spinal hæmorrhage is much more rare than cerebral hæmorrhage. Dr. Abercrombie had met with only one case of it. He gives the heads of seven

others which have been recorded by different authors. Dr. Bright has never seen it: but he publishes the particulars of one case, which was communicated to him by Dr. Stroud.

I will read you one or two short examples of spinal hæmorrhage, as specimens. A girl, fourteen years old, was attacked with headache, *pain in the back*, and a tendency to sickness when in the erect posture. At the end of a week the pain in the back became suddenly and very greatly aggravated; and this was followed by general convulsions, which proved fatal in five or six hours. The spinal canal was found filled with extravasated blood, in the lumbar region, where she had felt the pain. The brain and all the other viscera were sound. The case is detailed by Mr. Chevalier in the third volume of the *Medico-Chirurgical Transactions*.

Take one more instance from Ollivier, whose work on the spinal marrow you may read hereafter, when you have leisure, with advantage.

A gentleman, aged sixty-one, had just arrived in Paris after a long journey, when he was seized with *pain of the back*, all the way down from the cervical vertebrae to the sacrum. In the course of a few hours he became paraplegic, and was unable to retain his urine or faeces. He then sent for a physician, and died while talking to him. A very extensive extravasation of blood was found in the spinal canal, beneath the membrane of the cord. The lower part of the canal was filled with a bloody mass, in which the substance of the cord could not be distinguished. Above the third dorsal vertebra the cord was entire, but of a deep-red colour, and very soft.

The *suddenness* of the symptoms may lead you to suspect the true nature of these cases; but I cannot pretend to point out any other feature by which they may be distinguished from other morbid conditions of the spine, already spoken of. I show you one

preparation; of which, however, I do not know the history.

I have nothing to add, to what I have already said, respecting that species of palsy which is called *hemiplegia*: and I have only a very few farther observations to make in regard to *paraplegia*.

Paraplegia.—The cause of this kind of palsy is sometimes obvious; sometimes most obscure. If we find, in the spinal canal, blood effused, softening of the substance of the cord, traces of inflammation of its investing membranes, tumors pressing upon it, pressure from disease or displacement of the bones, we have a sufficient explanation of the paralysis of those parts of the body, the nerves of which come from the spinal marrow at or below the place of the disease. There are three preparations on the table of tumors that pressed upon the cord; scrofulous tumors I believe they are: each of the three persons from whose bodies they were respectively taken was more or less completely paraplegic.

But in very many cases we detect no alteration that seems adequate to explain the paraplegia. The palsy creeps on slowly and insidiously, without any particular pain, or violent symptoms: there is no tenderness or bending of the vertebræ. The weakness commences mostly in the legs, which appear to the patient heavier than usual, and of which the healthy sensations are often perverted. The toes tingle, or are numb: he experiences a feeling in them as if a number of ants were crawling on the skin. This is so common a circumstance as to have given a name to the symptom, *formication*. The patient straddles as he walks. His legs are lifted awkwardly, the toes being often the last part to quit the ground: they are then flung obliquely forwards and outwards, and the feet flap down heavily and uncertainly at every step. By degrees the weakness of the lower limbs increases: the palsy creeps upwards, affects the bladder and rectum, at length invades the arms, and ultimately the patient dies: yet very faint traces of disease, or no traces at all, may be visible upon inspecting the brain and spinal cord.

Very recently I had a patient with these symptoms in the Middlesex Hospital. He went out contrary to my wishes; he was discharged, in fact, by mistake: he took refuge in St. Bartholomew's, where he died after a few days. I have been informed that serum was found beneath the arachnoid, and that the whole brain had a wasted appearance; but nothing satisfactory was made out. The palsy had by slow degrees ascended from his legs to his arms; he had had no head symptoms beyond some occasional confusion and vague uneasy feelings there.

At this present time a patient in a similar condition comes to the hospital every Thursday, dragged by a friend in a hand-chair. He looks very well in the face, but is palsied below.

It is in these cases that you may expect to witness the very remarkable phenomena which I mentioned before as evincing the separate existence of a "true spinal marrow," distinct from the brain and its prolongations into the spinal canal, endowed with special and peculiar properties, and performing functions that are independent of sensation, consciousness, or the will. If you pinch or tickle the surface of the paralytic limbs, particularly about the feet, they will, in many cases, start up and move strongly, not only without any voluntary effort on the part of the patient, but in spite of him, and even (in those instances in which there is anæsthesia as well as palsy) without his knowing it. The legs often spring up *of their own accord*, as it seems; but, no doubt, the apparently spontaneous movement is frequently an excited movement, and takes place in obedience to the law that governs the automatic motions of the body. Some impression, made first upon the peripheral extremities of afferent nerves, runs through the nervous arc of communication, and exhibits its ultimate effect at the extremities of the corresponding efferent motor nerves. We can imagine many such accidental and unsuspected sources of excitement; a casual touch, the varying contact of the bed-clothes, the bite of a flea for aught I know to the contrary, may suffice. Even the passage of fæces or flatus along the lower bowel, or of the urine through the urinary passages, may be enough (as we are taught by unquestionable facts) to produce these movements. They are more readily excited, *cæteris paribus*, in proportion as the interfering influence of the will is more completely cut off.

I knew a gentleman, who had retired from the medical profession, and who, though not paraplegic, laboured, I believe, under some morbid condition of the spine. He had been, in early life, a hard drinker, and had suffered delirium tremens. Every night, sometimes more than once or twice, the trunk of his body, and all his limbs, became for a while fixed and stiff, from rigidity of the muscles. He told me this curious fact. Whenever he scraped his shoes on the scraper at the door, his leg flew up, with a spasmodic suddenness, from the iron, notwithstanding his endeavour to prevent it. I believe he was found dead in his bed.

In some cases of paraplegia involuntary retractions of the palsied limbs can be excited; in some cases they cannot. When the influence of the cerebrum is quite ex-

cluded by the operation of disease affecting the spinal cord itself, then is the susceptibility of excited movements the most lively. But the increased susceptibility, which has this inverse relation to the voluntary power, is limited to that portion of the body, the nervous arcs belonging to which lie beyond the seat of the disease; more distant, I mean, from the brain. Hence it follows that we may determine, approximately, the place of the disease, by the test of these reflex actions. The mischief may be situated, or may extend, so low down, that there are no uninterrupted nervous arcs below it. Supposing it to lie as low as, or to reach, the commencement of the cauda equina, we should have no involuntary movements. Conversely, when no involuntary movements can be excited, the spinal disease is, at least, as low as the upper lumbar vertebræ. Thus, I say, we have another mode, in addition to those pointed out in a former lecture, of determining, in a given case of spinal palsy, whereabouts, or to what extent, the cord is implicated in the disease.

We do not so often observe these reflex movements in cases of hemiplegia; apparently for this reason, that in hemiplegia the sensorial influence is not, usually, so completely shut out as it is apt to be in paraplegia. Yet I have seen some of these phenomena in hemiplegic patients. One of them, whose right hand and arm were quite passive under the strongest efforts of his will to stir them, took notice himself, as did his nurse, that whenever he yawned and stretched himself the fingers of the palsied hand participated in the action, and were thoroughly extended: and I could, by tickling the sole of his foot, excite some starting of the leg, long before any power of voluntary movement returned.

Do not forget the important fact that, in these cases of paraplegia, the urine generally becomes ropy, alkaline, and stinking; and that the bladder, after death, presents appearances such as chronic inflammation might produce; roughness and redness of its inner surface, and thickening of its coats. What is the order and relation of these changes, I confess I do not know: whether the quality of the urine is first altered, and then the bladder suffers from the perpetual contact of this unnatural secretion; or whether the bladder becomes diseased in consequence of the palsy, and pours forth unhealthy mucus, whereby the quality of the urine is affected; has not, I believe, been clearly ascertained. The first of these two suppositions seems to be the most probable. I fancy, indeed, (but I am not sure) that the urine remaining in the pelvis of the kidney in some of these cases has been found to be alkaline. Perhaps the disorganization of the bladder, and the alkaline state of the

urine, may both be common results of the interruption of the nervous influence.

We have reason to believe that the defect in some of these cases of paraplegia is merely functional: independant, I mean, of any such change in the nervous matter as is cognizable by our senses. It may be brought on by various causes: by cold; by intemperance in drinking; by excessive sexual intercourse; or, still more surely, by self-abuse. I have had the latter cause assigned to me voluntarily by patients themselves. In such cases we may presume that the loss of function is confined to the spinal marrow. But there is another way in which paraplegia may be accounted for, although its physical cause is very liable to be overlooked. It may result from serous effusion into the spinal canal; which effusion may have originated *there*; or, what seems sometimes to be more probable, may have been poured out *within the cranium*, and descended by the force of gravity to the lower part of the cavity of the spine. Dr. Baillie read a paper on this subject before the College of Physicians: it is contained in the sixth volume of the *Medical Transactions*. He was not the first person to whom this mode of explaining certain obscure cases of paraplegia suggested itself; but he was the first I believe who published upon it. This effusion may very readily be overlooked. Commonly the brain is examined first; and no great attention is paid to the escape of fluid from the vertebral canal. It would be better to lay open the spinal cavity first, at its lowest part, and to puncture the theca, and then to observe what quantity of fluid runs out when the body is placed upright. There *should* be a *certain* quantity: but if *much* serum so escaped, we might conclude that it had existed in hurtful abundance during life, and had caused the paraplegia. In most of these obscure cases you may trace *some* head symptoms; giddiness, transient confusion of thought, loss of memory; and it really will be worth your while to make the examination in the way I have pointed out, whenever you have occasion to inspect the body of a patient who has died paraplegic.

I regret very much that I had not the opportunity of doing this in the case of the man whom I had been for some time watching in the hospital.

Cases, such as I have now been describing, are by no means uncommon. They are usually slow and tedious; and you will be called upon to administer to their relief. I need not repeat the caution which I have several times given, in respect to the condition of the bladder; you must take care that it does not become over distended with urine; and you must enjoin strict attention on the part of the nurse to keeping the patient clean and dry. Friction along the course of

the spine; blisters to the loins or sacrum, frequently repeated; issues; and electricity: all these means you will generally have opportunity enough for trying, and for regretting their inutilty. In such cases it is warrantable and right to give strychnia; a poison which mainly affects the spinal cord; causing, when given in an over dose, tetanic spasms of the limbs, with very little affection of the sensorium. I have heard of some striking instances of recovery from paraplegia under the use of this drug. I wish I could tell you that I had even *seen* such. I should not advise you to begin with a stronger dose of strychnia, or of the sulphate of strychnia, than the twelfth part of a grain every six hours: this may be gradually and cautiously increased, until it gives rise to twitchings of the limbs, or to some other obvious effect. The twitching is usually confined to the palsied limbs. This shews that it results from the agency of the remedy upon the excito-motory system, or true spinal marrow; of which the reflex function is always more readily exercised when the sensorium has lost its customary controlling power. When this symptom occurs, you had better go on with the same dose: it would be unsafe to increase it: and the progress of the case will soon inform you whether any benefit is likely to accrue from the continuance of the medicine. The out-patient now attending has taken the strychnia. It made the palsied limbs start and extend themselves; but no permanent power has been gained.

There is one other drug which I should recommend you to try in such cases; viz. the tincture of cantharides. It certainly has sometimes a very beneficial effect. Generally, when it does good, it acts as a diuretic; and Dr. Seymour has thrown out a suggestion that it is most likely to be useful in those cases of serous effusion into the spinal canal, of *spinal dropsy*, which I just now described. He recommends the tincture as a good diuretic in several forms of dropsy; and supposes that it benefits paraplegia by tending to produce absorption of the serum effused within the vertebral canal.

Moreover, there is another principle upon which this medicine may be sometimes advisable. Cantharides are well known to have a peculiar effect upon the bladder; which effect is doubtless produced by the corresponding part of the spinal cord. If, by means of the Spanish fly, we can excite, though but from time to time, the function of that part, we may obviate, in a great degree, the distressing consequences of incontinence of urine, arising from paralysis of the *sphincter vesicæ*. Dr. Marshall Hall relates a very interesting fact, bearing directly upon this point. A young lady had a tumor within the tenth and eleventh dorsal vertebrae. It gradually, but completely,

severed the spinal marrow, and induced perfect paraplegia. The bladder lost its power of retention. But on giving a dose of the tincture of cantharides the power of retaining the urine was always restored *for the time*. That power would cease, and again be restored, on suspending or repeating the medicine.

Dr. Hall remarks that the cantharides obviously acted through the segment of the excito-motory system left below the division of the spinal marrow.

The tincture may be given in half-drachm doses.

Facial palsy and facial anæsthesia.—The forms of paralysis that have hitherto been noticed are forms of *partial* paralysis. When the palsy is still more limited, although the epithet *partial* would be equally applicable, the term *local* palsy is more commonly used. There is one of these local palsies which is exceedingly interesting, and of much importance: I mean palsy as it affects exclusively one side of the visage; *facial palsy*. It is sometimes called, not very correctly, *paralysis* of the portio dura of the seventh nerve. The most common kind of facial palsy is indeed paralysis of the muscles supplied by that nerve. But the word *paralysis* is misused when it is intended to express any other loss of function than that of the faculty of motion in muscular parts. It is incorrect to speak, as some authors do, of palsy of the kidney; it is equally inexact to speak of palsy of a nerve.

I say that *facial palsy*, and *facial anæsthesia*, (for the two should be considered together) are very *interesting* affections, because they elucidate, in the human subject, some of the most curious speculations of modern physiology: and they are *important* affections for you to study and understand, inasmuch as, though always distressful and alarming to the patient and his friends, they sometimes are merely inconvenient and disfiguring, and sometimes bespeak a condition of extreme danger.

Let us first consider that affection in which the majority of the muscles on one side of the face alone are palsied. I have already briefly touched upon this form of palsy when it constitutes a part of hemiplegia. But it is of more consequence to attend to it when it occurs without any similar affection of the limbs. When the arm, or leg, or both, are paralyzed at the same time with one side of the face, we know that the whole results from cerebral disease; but it is not necessarily so when the face alone is palsied; and it is often of great moment to the comfort and the safety of the patient, that we should be able to tell whether the palsy does imply disease within the skull, or not.

The appearance presented by patients

affected with facial palsy is peculiar, and very striking. From one half of the countenance all power of expression is gone; the features are blank, still, and unmeaning. The other half retains its natural cast, except that, in some cases, the angle of the mouth on that side seems drawn a little awry. This is apt to be mistaken for proof of a spasmodic condition of that part; but it is owing simply, as I stated before, to the want of the usual balance or counterpoise from the corresponding muscular fibres of the palsied side. The patient cannot laugh, or weep, or frown, or express any feeling or emotion with one side of his face, while the features of the other may be in full play. One half of the aspect is that of a sleeping, or of a dead person; the other half is alive and merry. The incongruity would be ludicrously droll, were it not so frightful also, and distressing. To the vulgar, who do not comprehend the possible extent of the misfortune, the odd appearance of such a patient is always a matter of laughter and merriment. On the other hand, his friends and relations imagine that he has had a fit, and are in great alarm for his life. In the majority of these cases there is not, however, any real danger of that kind to be apprehended; a circumstance which, of itself, would render the exact diagnosis of the complaint peculiarly interesting. In general there is no deficiency of sensation. And we sometimes have loss of sensibility in the same parts, without any diminution of the power of motion. The best way, I believe, to place the phenomena of these curious affections plainly before you, will be by examples.

A house-maid, Jane Smith by name, twenty-eight years old, became one of my out-patients at the Middlesex Hospital, with the following symptoms. She had lost all power of moving the right side of her face. When she endeavoured to raise her eyebrows, the right side of the forehead remained smooth, and the left was wrinkled. When she attempted to close her eyes, the right eye was but partially covered, the eyeball rolling upwards, and carrying the cornea within the curtain of the upper lid, which descended a little to meet it. When she tried to snuff in air through the nose, not being able to keep the right nostril stiff and open, its sides came together, and no air passed up on that side. When she smiled, the right side of the face remained perfectly still, like a mask; and it wore at all times a vacant and inanimate character. When she was told to perform the action of blowing, her right cheek was puffed out like a loose bag, and the breath issued, whether she would or no, at the right angle of her mouth. The same thing happened with her food and drink; she could not prevent their escaping at the

right corner of her mouth: nor could she convey morsels of food from the right to the left jaw, without the aid of her hand applied externally in support of the paralyzed cheek. The masseter and temporal muscles, however, acted as strongly on the one side as on the other; she could chew perfectly well on the palsied side, and the sensation of the palsied parts remained perfect; and there was no paralysis of any other part of the body.

All these phenomena are invariably met with in all well-marked cases of this kind. I will contrast them with the phenomena presented by another of my patients, who was in the hospital, and whose name was Ann Church. I give their names, that I may the more readily distinguish the one from the other. When this woman, Church, applied for admission, she complained of intense pain, with some swelling, of the right temple, and extending thence generally over the right side of the face and head. It was soon discovered, however, that although she complained of most severe pain in these parts, they had entirely lost their ordinary sensibility to external impressions. She felt nothing when her forehead, or cheek, or nose, or chin, was touched on that side. In short, there was complete *anæsthesia* of the right half of the face; just as in Smith's case there was complete *palsy*. The insensibility was very exactly limited to the right half, and terminated abruptly at the mesial line. It was remarkably evident in a part in respect to which the bystanders could scarcely be deceived, even if there had been any reason (which there was not) for distrusting the patient's own statement. The surface of the eyeball is proverbially sensitive, even to slight impressions. But you might place your finger upon this woman's right eye, or you might brush it with a feather, without giving her the smallest pain, or producing any sensation at all: whereas, on the left side, the lightest touch caused involuntary shrinking, and closure of the eyelids, and a gush of tears. She declared also that she had no feeling in the right half of her mouth: she neither tasted sapid substances, nor was at all conscious, from any sensation produced by them, that they were placed there. Her lips, on the same side, were equally destitute of sensibility; so that when she drank, having no perception of the contact of the cup with her lips beyond their middle point, she felt as if she were drinking from a vessel with a broken rim. This is a circumstance which all persons who are thus affected are much struck with; and it almost always forms a part of their voluntary account of themselves.

Besides this defect of sensibility, the power of contracting the masseter and temporal

muscles on the right side was entirely abolished in this patient. You may deceive yourselves on this point, if you do not investigate it carefully, and with certain precautions. At least I have known persons doubt, because, having directed the patient to open and shut his mouth, they have confounded the movement of the whole jaw with the action of the masseter muscle. But if you tell the patient first to close his mouth, and then to perform the action of grinding with his teeth, placing your fingers at the same time on the corresponding muscles on each side, the difference, when it exists, will be very striking. In the woman of whom I speak, no swelling of the masseter or temporal muscle on the affected side took place when she forcibly closed her jaws. There was no other paralysis.

Now we cannot separate the physiology from the pathology of such affections as these. Nor ought we. The morbid conditions of which the two cases just described furnish samples, illustrate in a very beautiful manner the modern doctrine respecting the special uses of particular nerves. In the first of the two cases the palsy resulted from suppression of the function of the hard portion of the seventh pair of cerebral nerves; and the anesthesia, in the last of the cases, depended upon suspension of the function of the fifth pair. You know that experiments performed upon living animals have proved that the division, by the scalpel, of the *portio dura*, before it spreads out into that remarkable nervous network on the side of the face, paralyzes all the muscles the combined play of which gives variety and significant expression to the countenance; and that, on the other hand, the division of the fifth nerve deprives the same parts of their sensibility. In these two cases, and in such as these, for they are by no means infrequent, a similar set of experiments upon the same nerves, in the *human* living body, is performed before our eyes by the agency of disease, or accident: and the result justifies most completely those conclusions which had been deduced in the first instance, from contrived observations made upon the lower animals.

There is one point in the history of these cases upon which I must dwell a moment longer; for it is a most interesting point. That the condition of the temporal and masseter muscles should be reversed in two patients so oppositely situated, was no more than might have been expected. But in each these muscles were affected in a manner the very contrary of that which the general circumstances of the case would, *à priori*, have prepared us to anticipate. Where the superficial muscles were paralyzed, and the principal movements of the face suspended, there the masseter and temporal muscles were in

full power and action; and where the loss of sensation was the predominant phenomenon, and the ordinary motion and expression of the countenance remained, there these muscles were in a state of complete palsy.

A few years only ago, this difference and apparent inconsistency would have been quite inexplicable. The progress of modern science has removed the difficulty, by establishing a general agreement between the *functions* of different nerves, and certain observed peculiarities in their *anatomical relations and arrangements*.

Suffer me to remind you (for I know that these interesting points of physiology must have already been taught you) that the nerves which proceed from the spinal column on each side are connected with it by two fasciculi of nervous fibrils—two *roots*, as they are metaphorically called—of unequal size; that when the larger of these, which is situated posteriorly, and is furnished with a ganglion, is divided in a living animal, the parts to which the nerve is distributed lose the faculty of sensation, while the power of voluntary motion remains unimpaired; and that when the smaller and anterior, which has no ganglion, is alone cut, the same parts are instantly palsied, but retain their sensibility. In other words, the posterior fasciculi minister to the faculty of sensation, the anterior to that of motion.

Now the fifth pair of nerves was observed to have a similar origin; to be composed, that is to say, of two fasciculi or roots, one larger than the other, and invested with a ganglion; the other smaller, and having no ganglion. It was natural to infer that the functions of these roots would be analogous to those of the corresponding portions of the spinal nerves; that the ganglionic fasciculus would relate to sensation, and the other to motion. And such is found to be the case; and the arrangement here is really very curious. The smaller portion of the fifth nerve is exclusively expended upon a very few muscles; viz. the masseter, the temporal, the two pterygoid muscles, the circumflexus palati, and the tensor tympani. The action of the two first of these, of the masseter and temporal muscles, is obvious to common observation; and therefore their condition is noticed in such cases as I have related. Again, these very same muscles have been shown, by careful dissection, to receive no nervous branches from the seventh nerve, which is a motor nerve, and which ramifies so abundantly upon the superficial muscles of the face.

It was to be expected, therefore, that any diseased state confined to the *portio dura* of the seventh nerve, would leave the temporal and masseter muscles fully effective: and that disease involving the fifth nerve, but leaving the seventh untouched, would destroy,

not only the general sensibility of the face on that side, but also the power of contracting these particular muscles. And this was thoroughly exemplified in the two cases that I have detailed. The girl Smith had total palsy of the superficial muscles; but sensation, and the action of the deeper-seated muscles, continued perfect: while in the woman Church there was default of sensibility, and paralysis of the temporal and masseter muscles; but the movements of the superficial muscles were unimpeded.

Every interruption of the function of the portio dura will paralyse these superficial muscles of the face: and such interruption may be occasioned either by *sudden injury* done to the trunk of the nerve; or by *disease* affecting its proper structure; or by *pressure*, the consequence of disease in the parts contiguous to it. And it is of great importance to observe that the morbid condition which causes the interruption may be situated in any part of the course of the trunk of the nerve: while it is yet within the cranium; or during its passage through the petrous portion of the temporal bone; or after it emerges upon the face, through the stylo-mastoid foramen, to be ultimately spread in meshes over the cheek and temple. The nerve is often compressed or hurt while still within the skull; but in *most* cases of this kind other portions also of the nervous matter are involved in the mischief, and other sets of voluntary muscles testify this by their immobility or their irregular action. This is sometimes the case when facial palsy occurs as a part of hemiplegia. In many instances, however, of hemiplegia, there is but slight distortion of the countenance, a mere hanging of the cheek, with no paralysis of the orbicularis muscle of the eye. In these cases, it has been suggested to me by my colleague, Dr. Todd, that the seventh nerve is probably not affected at all, but the motor branch of the fifth nerve only. When the *facial muscles alone* are paralysed, it happens in a great majority of instances that the nervous function is interrupted in that part of the portio dura which lies incased in the bone, or in the more exposed part which issues in front of the ear: and hence it arises that this particular form of palsy is, in general, unattended with any danger to life.

The physical cause of this remarkable disfigurement, and the true explanation of its prevailing immunity from danger, were first pointed out by Sir Charles Bell: but both the existence of the malady as a distinct form of disease, and its comparative harmlessness of character, had been observed and described some years previously: although the reason of neither the one nor of the other was at that time understood. Dr. Powell had narrated, in the fifth volume of the *Transactions of the*

College of Physicians, three marked instances of this form of local palsy; and had noticed at the same time its apparent independance of any apoplectic tendency, or cerebral disease.

The exciting causes of the complaint are various. Sometimes it is the consequence of mechanical violence, by which it is plain that the nerve has been lacerated, or otherwise injured. Sir Charles Bell, to whom we are indebted for much information on this subject, mentions several examples of this kind. In one a man was shot by a pistol ball, which entered the ear and tore the portio dura across at its root. In another, the patient was gored by an ox; the horn of the animal entered beneath the angle of the jaw, and came out in front of the ear, tearing the nerve across. In a third, the nerve was divided by the surgeon's scalpel, in an operation for the removal of a tumor which lay above and around its course. In all these cases the injury was external and obvious. In a fourth the palsy followed a blow on the ear which caused hæmorrhage from that part: here probably the nerve was hurt in its passage through the bone. Some time ago, a man was brought into the Middlesex Hospital who had fallen from a height, upon his head. The muscles of the left side of the face were paralysed. He died in a few days; and examination of the head shewed a fracture in the base of the skull, passing through the petrous portion of the temporal bone, and rending the seventh nerve at its entrance into the meatus auditorius internus. In the year 1832 I had a patient (Richard Hills) in the hospital with the same kind of paralysis, which seemed, in him, to have been occasioned by a mere shock, or jar. He was a coachman, and one day, when he was off his box, his horses started away, and ran to their heads to stop them, but he was thrown down in the attempt, striking his hip and elbow. He received no blow on the head at all. Three hours afterwards he found that he could not *spit* properly. The affection is not unfrequently discovered by that circumstance. He could not avoid spitting on his clothes on one side; and he could not whistle. Another circumstance worthy of notice took place in this man, which often, though not always, happens in these cases, and which I did not mention before. He remained for about two months in the hospital; and regained during that time in some degree the power of exercising the affected muscles; but he still was unable to close the right eyelid. The eye itself was unharmed. After he was made an out-patient he resumed his functions on the coach-box; and his eye, permanently half open and unprotected, was more exposed to cold and to currents of wind than it had been when he was an in-patient. Moreover

he got drunk; and he soon presented himself again with universal redness and inflammation of the conjunctiva. Sometimes the inflammation in such cases produces opacity of the cornea and a total loss of vision. This is one of the worst consequences of facial palsy. Fortunately it is only an *occasional* consequence; and it will occur or not, according to the quantity of motion which remains to the eyelids, and the degree of exposure to the ordinary causes of inflammation.

Sometimes the palsy depends upon manifest *external disease*; sometimes upon disease which is hidden, and probably *internal*, in the bony canal. Sir C. Bell describes an instance in which it accompanied the disorder called the mumps. Dr. Madden, of Worcester, witnessed another in which a fixed, hard, indolent tumor, had formed between the ramus of the lower jaw and the mastoid process of the temporal bone. As this tumor gradually subsided, the palsy disappeared. In each of Dr. Powell's three cases the affection was apparently caused by exposure of the side of the head for some time to a stream of cold air. A medical acquaintance of mine, residing in London, had a patient at Greenwich whom he visited daily. It was cold weather; and on one occasion, as he was returning in the cabin of a steam-boat, he was sensibly incommoded by a keen east wind, which blew through an open window directly upon his ear. The next day he presented himself to me with that side of his face fixed in the manner I have been describing. Exactly the same mishap befel a Scottish physician while travelling to London by a coach; and sent him in great alarm to Sir C. Bell. Six years ago a marked example of facial palsy occurred in one of my hospital patients: it appeared to be owing to his having been constantly in the streets for some days without shoes or stockings, during a cold thaw. It may be presumed that in these instances some swelling was produced in the soft parts around the nerve, compressing it where it lies within the unyielding bone. Exposure to cold in this way is the commonest of all the exciting causes of the complaint, and cases thus arising are more obedient to treatment than most others. Probably some of you saw a female patient who came under my care in the hospital in May last, (1838), in whom facial palsy had existed on one side for eighteen years. When about three years old she had the measles; and a scrofulous tumor formed behind the ear, and broke; and after some time, a portion of carious bone came away. Then the wound healed (of which deep traces are still visible); and the peculiarity of her features was observed. There are still other cases in which we fail to discover any direct explanation of the paralysis, either in the his-

tory of the patient, or in his physical condition. In the girl Smith, whose symptoms I stated in detail as an example of the appearances uniformly present, the malady came on without any obvious cause, and it resisted all the means employed for its removal.

That the greater number of cases of this kind are free from serious peril, is a fact of great practical importance. It enables us to quiet the alarm of the patient and his friends; and it regulates in many instances the *treatment*; rendering it less severe than it might and ought to be, if the palsy were really the harbinger of apoplexy. At the same time you should not be ignorant that a similar limitation of paralysis to the particular muscles supplied by the portio dura is sometimes (though rarely) observed, when the disease has a more inward origin; when it affects and involves the brain itself. The following case caused me much anxiety, for the subject of it was a personal friend of mine:—I was summoned to his house in the autumn of 1829, and found him with complete palsy of the left side of the face, which had existed a day or two. I shall not describe the appearances and symptoms that resulted from the paralysis; for they were precisely the same as were presented by the girl Smith; and they are always, and necessarily, very much alike. But though the *palsy* was strictly limited to this set of muscles, there were other symptoms present which indicated that the interruption of the functions of the portio dura was connected with some morbid condition within the cranium: nausea and vomiting, twitching of the muscles of the *other* side of the face, great drowsiness, and a slow pulse, 48 only in the minute. He lurched also, and staggered as he walked; but he distinguished this from the reeling of vertigo, and denied the latter sensation altogether. He was deaf, too, on the affected side.

His previous history did not tend to diminish the fears which his actual state excited.

In the preceding February he had been attacked, rather suddenly, with intense pain just above the right eyebrow, and became extremely drowsy. Being desirous, on account of these feelings, to excuse himself from a dinner engagement, he found that he was unable to write a proper note: he could not remember how he ought to express himself.

All these symptoms soon passed off; after the operation, I believe, of an emetic. But he had another attack of the same kind in the subsequent May: the same severe pain over the right brow, with great drowsiness and confusion of mind. He could not recollect the first line of the *Æneid*. He wished a friend to look at the *signatures* of some letters that

had arrived: and though he knew the root, he could not tell how the word he wished to use was formed; whether it was *signition*, or *signation*, or *signature*. The digestive organs on this occasion were made the object of treatment; and he soon got well.

There was another instructive part of his history; and therefore I mention it. Before these attacks he was in the habit of eating and drinking freely; and his power of digestion was supposed to be enormous. After the attack in May he commenced a strict course of temperance. He drank no wine *till three or four days before* the occurrence of the facial palsy: he had then taken it again, and had about four glasses daily; and on one of the days he drank two glasses of Champagne.

It was of some moment to this gentleman, not only that he should recover, but that he should recover quickly. He had been appointed by Government to a mission to Ceylon, and all his equipment was already on board a vessel, which would sail in a fortnight.

Cupping behind the ears, blistering, purgatives, and small doses of calomel continued till the gums were slightly sore, removed the paralysis, and all the other symptoms, in about ten days. He went to Ceylon, and performed his mission so ably that after his return the Government appointed him to one of far greater importance in India, where he now is. He has remained perfectly well; and possesses one of the clearest and strongest intellects that I am acquainted with.

I must trouble you with one more case, to complete the history of this disease: a case in which the cause of the facial palsy was situated within the cranium, and proved fatal, and became visible after death.

Samuel Dovey, a tailor, 57 years old, was admitted under my care into the hospital, in February 1833, with complete palsy of the muscles supplied by the portio dura on the right side; and of no others. There were symptoms enough, however, to shew that some serious mischief was going on within the skull. He suffered intense headache, more on the left than the right side; was dizzy and staggering; and could not get to the ward without being led.

The palsy had come on about ten days before, in the night. He found when he came down stairs the next morning that he could not spit as usual; and his friends observed the unnatural state of his features. He had had no fit, nor loss of consciousness; but he thought his memory was failing. At the time when the paralysis was first noticed, he had some numbness and tingling of the right arm, extending to the last two fingers. He was quite deaf in the right ear. This is a point deserving attention in such cases. The deafness, when it occurs, marks an

affection of *both the portions* of the seventh nerve; and therefore indicates the probability of an *internal* cause.

The whole progress of this case was very interesting; but I must confine myself to those circumstances which bear upon our present topic. He lived about a month after his admission, and during that interval he suffered great pain in the head, was delirious at times, and at other times in a state of coma: at one period he suddenly presented the ordinary symptoms of apoplexy, from which he partly recovered.

I found a cancerous tumor occupying the right hemisphere of the brain; at its under part was an apoplectic clot, as big as a hazel nut. I found also a very satisfactory explanation of the deafness and the facial palsy which had been noticed during his life-time. The portio dura and the portio mollis, where they emerge as distinct cords from the medulla oblongata on the right side, were adherent to each other. The portio dura was both harder and larger than the corresponding nerve on the opposite side, while the portio mollis was wasted and diffident. The same change was traced up to their entrance into the petrous portion of the temporal bone. Immediately over the medulla oblongata, and in a vertical line above the point of emergence of the seventh pair of nerves, a nipple-like portion of brain projected downwards, and had apparently communicated pressure to these nerves; and this projection from the lower surface of the brain seemed to have been produced by the general pressure resulting from the growth of the tumor.

The remarks which I have been applying to *palsy* of these parts hold true also in respect to their *loss of sensibility*. The anesthesia may or may not portend danger to life, according as the interruption of nervous function on which it depends is situated more or less near to the origin of the fifth pair of nerves in the brain. The patient, Church, whose case I have several times referred to in this lecture, left the hospital with the sensibility of her face nearly as perfect as ever. The treatment consisted in local blood-letting and counter-irritation. She had erysipelas of the head while in the hospital, and was in some danger from that complaint, which was attended with a good deal of fever and delirium. With the exception of the delirium, which belonged no doubt to the erysipelas, there was no reason to suspect any affection of her brain.

Treatment of facial palsy.—I have incidentally adverted to the plan of treatment to be pursued in these cases of facial palsy. When the complaint is recent, and has an obvious cause, the appropriate remedies will readily suggest themselves. When, for example, it has come on after exposure to a

current of cold air, or after a blow, or any circumstance likely to give rise to inflammation, you must treat the case as you would treat inflammation; bearing always in mind that a small amount of disorganization, a little thickening or induration of the parts around the nerve, may render the deformity and the inconvenience *permanent*. If there be inflammatory fever, bleed from the arm: if there be not, take blood from the neighbourhood of the affected nerve by cupping: apply fomentations; or, what is better in these cases, conduct the steam of hot water against and into the ear: and administer mercury so as just to touch the gums. I should always take this latter precaution, lest any effusion of lymph should cause abiding pressure on the nerve. If the palsy gives way before the gums become tender, the mercury need not be pressed farther.

Where there is any ground to suspect that the brain is implicated, the treatment just described must be pursued with greater diligence, and with such modifications as the nature of the case may require. If there be evidence of chronic disease in the petrous portion of the temporal bone, such as tenderness of the mastoid process, deafness, a protracted discharge from the ear, and an imperfect state of the *membrana tympani*, we can scarcely expect much good from very active treatment. We must then have recourse to counter-irritation, and such other measures as I spoke of when the subject of otitis was briefly considered.

Other forms of local palsy and anæsthesia.—The examples which are met with of local palsy, and local anæsthesia, are numberless; but those which I have mentioned are the most common and the most important. They are always deserving of attention; but more so when any suspicion arises that they may be connected with cerebral disease. Sometimes they evidently have no such connexion. In the month of November, 1834, a coachman became my patient in the hospital with imperfect paralysis affecting some of the muscles of the right foot alone, with numbness of the foot. He could both stand and walk; but on advancing that leg, his foot flapped suddenly down, and he could not deliberately direct and plant it, like the other. His general health was quite good; he had no headache, or giddiness, or palsy of any other part. But a month before he had been sitting with the right leg thrown over the opposite knee; and he continued in that position until the foot felt numb, tingling, and was (what is called) asleep; and it had remained in the same condition from that time. After some general treatment (cupping and purgatives) before he came to the hospital—treatment which was quite proper in the way of pre-

caution, but which was probably, in truth, unnecessary—I had his leg electrified; and in about ten days the sensation and the power of the limb were almost restored. Mr. Swan mentions a somewhat similar case, in which anæsthesia of the hand was produced by strong pressure made upon the wrist.

There are some very curious facts, connected with anæsthesia, shewing that the voluntary exercise of the muscles is regulated in some measure by the sensations of the limb that is employed. The sense of resistance prompts to such contraction of the muscles as is required to balance that resistance; reminding the will (so to speak) of the necessity that exists for its perpetual and vigilant operation. Continued volition is essential to the continuance of the muscular tension. Thus Dr. Yelloly describes a woman who had no power of feeling in her hand and fingers, although the power of moving them, and of grasping any objects, was entire. This woman found that she could carry glasses or plates in that hand very well and safely, if she continued to look at and attend to them; but if her eyes were turned another way, as she did not feel what she held, she was very apt to drop it. Dr. Ley met with just such another case. A woman had defective sensibility on one side of the body: she could hold her child in the arm of that side so long as her attention was directed to it; but if surrounding objects diverted her from taking notice of the state of her arm, the flexor muscles soon began to slacken, and the child was in danger of falling. All this is exceedingly curious.

Andral has recorded a most singular example of local anæsthesia, which preceded an attack of apoplexy. The patient lost, from time to time, all sensation in certain isolated parts of the skin upon the thorax; there were five or six of these insensible spots, each about the size of a five-franc piece. You might pinch the skin in these places without producing the slightest feeling in the patient. In all other parts the sensibility was perfect and lively.

There are other cases also on record, more remarkable still; in which the patients have lost both the power of motion and the faculty of sensation in almost every part of the body, and yet have survived for a considerable time. Thus one person (whose case is related in the *Bulletin des Sciences Médicales* for Jan. 1828) became first amaurotic, then deaf, and then by degrees lost all power of sensation and motion except in the tongue and in the muscles of deglutition and respiration. His speech and intellects were unimpaired. It was accidentally discovered that a small patch on the right cheek retained its sensibility; and by

tracing letters on this sensible spot, his wife and children were enabled to interchange ideas with him. He died at length, and his body was not examined.

I shall finish what I have to say on this head, by relating a case of the same kind, which occurred under Dr. Abercrombie's notice; and which we are sure therefore would be observed with care, and recorded with fidelity.

A servant girl, about 20 years old, sprained her back in lifting some heavy article of furniture. She felt no great inconvenience at the time; but some little while after, weakness of the legs came on, and gradually increased to perfect paraplegia. After an interval, the affection extended to the arms, and she then had not a vestige of motion of any of the parts below the head, except a very slight movement of one of the fingers: but the internal functions were all perfect, and her speech was distinct, except that in speaking she was sometimes seized with spasmodic twitches of the lips and lower jaw. She lived in that state, without any change of the symptoms, and her general health continuing good, for about twenty years. In the morning she was taken out of bed, and placed in a chair, so contrived as to support her in a sitting posture. Her arms rested on a cross board which passed before her; and if by any accident one of them slipped from this support, she had no resource but to call the assistance of another person to replace it. Having been on one occasion left alone for about two hours after one of her arms had thus slipped down, the hand had become extensively oedematous. In the same manner, if her head fell forward upon the thorax, it remained in that position until raised by an attendant. Her mind was entire. She died after four days illness with symptoms of low typhus fever. You may suppose that Dr. Abercrombie looked with the greatest interest for the cause of these most remarkable symptoms. "I examined the body with the utmost care, (says he) along with Dr. Pitcairn, who had been in the habit of seeing her for several years; and we could not discover any disease, either in the brain or in the spinal cord."

It is much to be regretted that when this case was under observation, the excitomotor functions were not understood, nor attended to.

I shall next proceed to consider those diseases (and there are several of them) which are marked by definite symptoms, which consist essentially in some disturbance or disorder of the nervous system, but which are not accounted for by any physical changes that we can appreciate in any part of that system. After some of these diseases we do, to be sure, sometimes meet

with morbid appearances in the brain and spinal marrow: but none that are constant, or uniform.

CLINICAL LECTURES,

BY DR. CORRIGAN,

Delivered at the Hardwicke Fever Hospital, Dublin,

During the Session, 1840-41.

LECTURE V.—FEVER, No. 3.

Nature of Fever, and principles of its Treatment—Rate of Mortality—Importance of attending to the State of the Bladder, and Necessity of using the Catheter.—Certain Remedies to be avoided, particularly Bleeding, Sudorifics, & Purgatives.

WE have, I hope, by our observations of last day's lecture, in some measure cleared the way for an understanding both of the nature of fever, and of the principles of treatment, to which we shall devote this day's lecture.

Before presuming to recommend any particular lines of treatment, it is only right to ascertain whether the results are such as to recommend it. I believe it will be found that they are. Mr. Edgeworth has been kind enough to draw up a table of the admissions and deaths, and causes of death, from July 1, when the wards came under my care, to December 31, a period of five months. The total number of admissions within that period has been 297; total number of deaths 12. Of these deaths there were from—

Scarlatina, 2, A. Prendergast, and E. Mulalley; pleuro-pneumonia, 1, Charles Doyle; pleuritis and empyema, 2, J. Finlay and T. Kavenagh; old age, 1, L. M'Keow; hydrocephalus, 1, Margaret Fitzgibbon; hæmorrhage, 1, Margaret M'Gregor; cholera, 1, Bridget Foran; meningitis, 1, John Neile. Total, 10. We have had during this period only two deaths from fever—Honor Walsh, æt. 22, who died on the 14th day; and Anne Mayne, admitted in a dying state. Our statistics for five months will then stand thus:—cases of maculated fever admitted, 287; number of deaths, 2: which gives us as our rate of mortality one death in 143½. This is a very favourable result, and the treatment under which it has occurred we shall now go into a little in detail.

There is one organ to the state of which I have repeatedly called your attention, and impressed on you the necessity of closely watching, viz. the bladder. The case of Murphy afforded us a good illustration on this point. He was very ill in maculated fever—so violent that it was necessary to put a strait-waistcoat on him. His delirium was furious: his tongue was dry and brown;

his pulse beating above 130; his skin covered with both maculæ of fever and petechiæ of purpura. He had not slept, and his eyes were suffused: he passed his fæces in bed, and we were positively assured by the nurse that he had also passed urine copiously under him. This report seemed to be confirmed at first sight on turning down the bed-clothes, for there was a strong urinous smell: the clothes were stained by the urine; and the urine was seen welling from the orifice of the urethra, and dribbling over the thigh. Notwithstanding all this I had the catheter introduced, and there were drawn off certainly not less, and I believe more, than two quarts of urine. You can easily conceive, were the bladder allowed to remain thus distended, what the ultimate effect on the system would be. It is hardly possible to suppose any thing more calculated to destroy life in fever than such a state of bladder; the organ so distended as to have lost its muscular power, and no urine passing off, save the surplus quantity which can no longer find room in the distended bladder. It is a rule of practice I would most earnestly impress on you in the treatment of fever, never to omit the introduction of the catheter in cases where there is either delirium or coma, unless you have the quantity of urine passed preserved for your own inspection. If, on the introduction of the catheter, there be no urine in the bladder, there is no harm done, and you have satisfied yourselves: if there be urine present you perhaps save your patient's life, by freeing him from the irritation produced by the distension of the bladder, and from the bad effect of the retention of so much excrementitious fluid, which, if not removed, will at least in part again be absorbed to his serious injury. Never in such cases trust to the report of the nurse as to the quantity of urine passed. Trust in nothing but the inspection of it; or, what is better, the test of the catheter. You may suppose that in such cases examination of the hypogastric region will be sufficient for your information as to the passing of urine, without the introduction of the catheter. Believe me, it is not to be trusted. I shall never forget a case that impressed this strongly on my mind. A gentleman, of low stature and full habit, was lying comatose from erysipelas of the head and face, and had for several hours passed no urine. Were I to mention the names of the gentlemen who were in attendance with me on the case, it would be a sufficient guarantee that the examination of the region of the bladder was made with care and tact, and the result of that examination was almost a conviction that there was no urine in the bladder, and that the case was a fatal one of suppression; still the catheter was employed, and a quart of urine was drawn off. The result of attention to the

bladder two or three times a day was the gradual clearing up of the coma, and the recovery of the patient. You might also suppose that percussion of the hypogastric region would be sufficient to detect urine in any amount in the bladder. It is not. Either from the natural inclination of the bladder, its being thrown more backwards in some persons than in others, from a degree of tympanites in the intestines, from the posture of the patient, who always, in the cases where the examination is most called for, has lain for many hours on his back, or from all those circumstances combined, there will be clearness on percussion over three-fourths or more of the hypogastric region; and yet the bladder will contain a large quantity of urine, which the patient, in the oppressed or debilitated state of his nervous system, will not pass. We have many times percussed the hypogastric region, and elicited a clear sound: and yet immediately afterwards drawn off a large quantity of urine. Even though the quantity taken away from the bladder be not very great, it is probable that there is a good effect produced by its removal. Its removal will probably encourage a free secretion from the kidneys; and a copious secretion of urine is one of the most favourable circumstances we can have in fever. The ultimate conclusion at which I think we must now arrive, relative to our consideration of the state of the bladder, is, that we ought to trust neither to the report of the nurse nor to the examination of the hypogastric region by the hand, nor to percussion, but only to the catheter, or to the inspection of the actual amount of urine passed from visit to visit. I do not think I can overrate the importance of attention to the state of the bladder in stages of fever where there is great nervous debility, coma, or delirium.

We shall now proceed with other parts of the treatment, and perhaps it may be not more necessary to say what treatment we have followed, than to point out what practice we have avoided. But let me not be understood as now presuming to recommend the line of practice at present adopted as applicable to fever in general; it is to be understood as applied only to the present epidemic of maculated fever. There are three active remedies which I have found it necessary to abstain from—general bleeding, sudorifics, and cathartics. General blood-letting has not been employed in a single instance; nor has there occurred one among so many cases where even a thought of its employment could suggest itself to the mind. This forms a very remarkable feature in our present epidemic, as it belongs, perhaps, not more to the character of the fever than to the state of the human constitution at large, at the present time at least, in this

country. The fact is obvious to every one of observation, that not only in fever but in other diseases, in acute inflammatory attacks, there is neither the same necessity now for active blood-letting that existed some years since, nor would it even be borne. In relation to the capability of bearing blood-letting or depletion under disease, there has occurred in the human constitution, within a period of some years, perhaps most remarkably since the invasion of cholera in 1832, a very marked change. This singular change in the human constitution, and which perhaps follows something like a regular cycle, is always first and most remarkably seen in fever, because fever engages more of the vital functions simultaneously than any other disease; and thus the phenomena of fever are deserving of our closest attention, not only for their own sake, but as affording an insight into modification of treatment in local affections. This singular change in the human constitution, and which as positively occurs as a change of climate or of season, affords us an explanation of those changes, or even apparent contradictions, in treatment, that are sometimes found in writers of different times. Those changes in the treatment of diseases, that have occurred from time to time, which are, for the reason already noticed, always most remarkable in fever, but which are also seen, in corresponding degree, in all local diseases, are occasionally alluded to by persons of shallow mind, or little comprehension, as evidences of changeableness and uncertainty of principles in the practice of medicine. If, while constitution and disease were running their cycle of change, our treatment, like Sangrado's, were always to remain the same—unsuited to constitution, unadapted to symptoms—then, indeed, the criticism might pretend to some show of truth. Those who would esteem a settled and unvarying line of practice to be suitable and best for all times and changes, exhibit as much sense as the savage lawgiver, who proclaimed that in all stages of changes of the social constitution his rules and laws should be immutable. These general observations may seem at first unsuitable to a clinical lecture. I do not think they are. I do not think the fact of the change which occasionally comes over the human constitution, and which always becomes most perceptible in disease, is generally sufficiently kept before the mind of the practitioner. Attention to it at the bedside is not less necessary than attention to the disease itself; and how soon the present type of disease and present constitution of the living system may change their characters, it is quite impossible to say. If we bear in mind that the change has already frequently occurred, and will certainly occur again, we shall be better prepared to detect it and to meet it.

Sudorifics come next as a treatment to be abstained from in our present epidemic. Of all crises or terminations of our maculated fever, that by perspiration is the most to be dreaded. Crises may take place imperfectly by urine, by sleep, even by diarrhoea, by any of these, even only by remission, and the case be even benefitted by the partial crisis; but if after the ninth or tenth day a copious perspiration comes on, and that the strength show the slightest tendency to sink under it, or, what is still worse, that the pulse rise in frequency while the perspiration is coming out, the termination will almost certainly be fatal. In fact, recovery under such circumstances is an exception. I have such a dread of the crisis by perspiration, that I would rather see the fever considerably prolonged than run even the chance of the consequences of perspiration. I am confident one of the causes for fever being more fatal in private life than in hospital is, that from the feather beds, the warm drinks, the heavier covering of private patients, there is in such patients a greater tendency to perspiration than in the cool wards, the light covered beds, and the cool drinks of the hospital patients. Every thing that can encourage perspiration in our maculated fever is to be avoided; and if the patient, as sometimes happens, has been in the habit of wearing a flannel vest, or dress, in bed, let it be removed. It sometimes requires the most peremptory order on the part of the physician to enforce those regulations. Popular knowledge, or rather ignorance, confounds the maculated or typhoid fever with the common inflammatory fever or synocha. A copious perspiration will cure a patient in the latter; it will probably kill in the former.

Purgatives are the third on our list of remedies to be abstained from, or to be cautiously used. We have used them very sparingly indeed. In by far the greater number of the worst cases we have never administered a purgative by the mouth, and there is this satisfactory result, that during a period of five months, in 287 cases of maculated fever we have not had a single case of urgent intestinal tympanitis. Among the complications of fever there is scarcely one more to be dreaded than a tympanitic state of the intestinal canal. Even without fever at all, as a mere local disease, distension and want of tone of the intestines, as in one form of ileus, is sufficient to kill. What, then, must be its danger in a constitution with not one, but every, vital function depressed to its lowest ebb. We are to estimate the value of any particular line of treatment in fever, not alone by the symptoms we can combat, but by the dangers we can prevent; and if by adopting a particular line of treatment the occurrence of a dangerous complication of fever is prevented, that line of

treatment recommends itself even more strongly than a line of practice which would permit the danger to arise, and then turn to combat it. There has been no necessity in our epidemic for the use of purgatives; the bowels have been almost always moderately free, or, if not so, or if a tendency to tympanites has shewn itself, an enema has always been sufficient for the purpose of procuring a discharge, or removing flatulence. We cannot cut the fever short by purging. We can do no good by it; but we may do much harm, both by lowering the strength considerably, and by producing mucous irritation. We had better, therefore, refrain from it; and this recommendation is supported by the best of all tests—the practical results.

Having noticed some practices to be avoided, we shall next turn our attention to treatment to be adopted.

AN ESSAY

ON THE

SOURCES OF TYPHUS OR CONTINUED FEVERS.

By JOSEPH BELL, Surgeon, Barrhead.

[Concluded from page 144.]

HISTORY from the earliest period informs us that fever has been a too constant attendant on war. This connection has become proverbial in Germany, where it is called war-pest (*Kriegspest*).

The continental epidemics have either accompanied or succeeded seasons of poverty and destitution. The fevers of Italy in 1764 and 1817 took place under circumstances of great want. The epidemic which raged at Louviers in Normandy in 1770, broke out under similar suffering. Lepecq de la Cloture informs us “that for a number of years the price of provisions had become extremely high, and that suffering having greatly increased, the commune of Louviers was considerably debilitated, which caused the manufacturers to stop a part of their work; consequently a number of operatives remained without employment, and the wages of others were diminished. What happened then? One did not see, as formerly, the workmen enjoying themselves on fête-days, and destroying a part of their care in wine. No; there were for them no more movements of joy. Sadness was painted in pallid colours on every countenance. Misery had crushed their spirit. In short, they

were reduced for the most part to deprive themselves of some of their miserable furniture; to dispose of them that they might satisfy their hunger, and to provide some morsels of bread to the urgent calls of their children.”

In Scotland the prevalence of fever has been also coexistent and coextensive with privation.

This appears evident from the following facts adduced by Dr. Alison:—

1st. “It appears, from observing the times of these epidemics, the first in Edinburgh beginning in 1817, after two bad harvests, and at the same time as the Irish one; the next in 1826, after the great failures in 1825, and the sudden cessation, particularly of building speculations, in Edinburgh; and the last in 1836, after the great depression of trade both in Glasgow and Dundee, with which towns the lower orders here are much connected, and under the combination of other circumstances already mentioned, which have depressed the condition of the poor in Edinburgh of late years*.”

In consequence of this depression, Dr. Alison argues, fever has been greatly on the increase. “For many years past,” he observes, “contagious fever has never been absent from Edinburgh, and there have been three great epidemics of that disease in the last 22 years, beginning in 1817, 1826, and 1836, each lasting nearly three years, and each of the last two affecting, I believe, nearly ten thousand persons. The number of fever patients admitted into the Infirmary and Auxiliary Fever Hospital, from November 1817 to November 1820, was 3090; from Nov. 1826 to Nov. 1829, it was 4318; and from October 1836 to October 1839, it was 4850.”

The increase of typhus has not been confined to Edinburgh. Some of the other large towns have suffered to a still greater degree, especially Glasgow. This will appear obvious from a glance at the Vital Statistics of Glasgow, by Dr. Cowan. According to this physician, the number of fever patients admitted into the Glasgow Royal Infirmary during seven years ending 1802, was 484. The following seven years 512 cases were admitted; and from this till 1816, a period of seven years, 574 were admitted. From 1816 to 1823, the number increased to 3866, and

* Management of the Poor, &c. p. 13.

the following seven years it rose 6075; and from 1830 to 1836 inclusive, the number of admissions amounted to 11,750.

This calculation, however, can be merely regarded as an approximation to the actual number of fever cases which occurred in Glasgow. The hospitals appropriated to the reception of patients labouring under fever are not adequate to admit the whole of the poor who are seized with the disease. Many cases must have also occurred among the better classes of society. That this increase of fever is owing to the same cause which produced it in Edinburgh, is quite evident from Dr. Cowan, as well as from the testimony of several others who have investigated the subject. It is true that Dr. Cowan states a circumstance which at first sight appears to oppose this view, but on a second consideration it will be found to have no such tendency. At p. 13 of his *Vital Statistics of Glasgow*, he observes, "This increase, especially during the last seven years, (from 1830 to 1836), has taken place, not in years of famine and distress, but during a period of unexampled prosperity—a period when the wages of labour have been ample, the prices of provisions comparatively low, and every individual able and willing to work, secure of steady and remunerating employment." This state of prosperity did not long continue, and has not yet returned. At page 34, Dr. Cowan informs us that "from the close of 1836, one of those periodical depressions in trade . . . deprived a large proportion of the population of the means of subsistence . . . a very large proportion of the inhabitants were suddenly deprived of employment, and consequently of the means of procuring food. The high price of coal was the means of diminishing the hours of labour, and consequently the amount of wages in numerous factories, and placed fuel beyond the reach of the lower classes for domestic purposes."

To these sources of destitution we may add the bad harvest of 1836, and consequently the high price of food during the latter part of that year, and the whole of 1837.

We perceive that the period of prosperity was prior to 1836: during the latter part of which year these privations commenced. We find that when

the people had constant employment, and obtained good wages, fever prevailed to a much less extent than it has done since. In 1835 the number of fever cases which occurred in Glasgow is stated by Dr. Cowan to be 6180; in 1836 it increased to 10,092, and in 1837 to 21,800.

The working classes of Glasgow were in the same destitute condition during the epidemics 1816-17-19. There was great stagnation of trade. The operatives were subjected to great suffering, especially hand-loom weavers; 5256 of whom were out of employment in 1819. And Dr. Cleland informs us that "in 1817, 23,000 persons applied to the charitable funds for relief."

From the foregoing facts we perceive that, between the increase and spread of fever and a state of destitution, there exists a very close connection—a connection which has been maintained since 1817, not only in Glasgow, but also in the other large manufacturing towns of Scotland. We shall only instance Dundee. Dr. Alison, after detailing the causes of destitution to which the working class of this town have been exposed since 1818, observes, "that prior to 1818 little demand was made, comparatively speaking, on the Dundee Infirmary for the reception of fever cases; but during that and the following year the disease raged to such an extent in town and suburbs, that the house became inadequate to the wants of the community. Since that period the progress of the disease has been various, but on the whole *vastly on the increase*. The last epidemic appears to have attained its maximum there in 1836, when the fever patients in the infirmary were 773, and the deaths from fever stated in the mortality bills (which I understand to be kept very accurately) are 297. But in the years 1836-7-8-9, fever continued very prevalent; and the whole number of deaths in these years having been 7160, or 1790 a year, in a population which in 1831 was 45,000, but is since supposed to have extended, chiefly however by accessions from the country, to above 60,000. From these facts we may infer that nearly 10,000 inhabitants of Dundee, or nearly one in six of the population, must have had fever in these four years."—p. 14.

Such, then, is the connection which has usually existed between the pre-

valence of fever and the existence of poverty.

I am convinced that the history of fever in the town of Paisley will afford an illustration of this relation. It has done so in the village of Barrhead for the few years that I have resided there. This is particularly the case at present. The population is chiefly composed of operatives, many of whom have been in very destitute circumstances for the last six months; and fever, which was rare previous to that period, has prevailed extensively since, principally among the poor; many of whom are in the most abject misery, having neither clothing, fuel, nor food. Since the month of August last, in one range of houses inhabited by 272 individuals, sunk into the depth of poverty, 61 cases of fever have occurred. In many of these instances no other source of fever could be traced on the most careful investigation, except poverty.

From the universal co-existence of privation and fever, which the mass of facts adduced in the preceding pages amply prove, we are justified to infer that these two evils frequently stand in the relation to each other of cause and effect. We have seen that wherever disaster and destitution prevailed for any length of time, affecting large communities or congregations of men, fever is a too certain and constant attendant.* We have seen, from ample experience, that in times of scarcity and of stagnation of trade, and disasters in military affairs, fever has raged with dreadful virulence. Many other circumstances corroborate the opinion that fever is frequently originated from privation. Do we not find large communities, placed under exactly similar circumstances as regards their habits of life, their mode of dwelling together in crowded and ill-ventilated apartments, surrounded by noxious effluvia? But those who compose some of these communities are found to suffer the pangs of hunger to an extent wholly unparalleled to the members of the others, where the poor are shielded from this abject misery. Do we not find that among the former fever prevails to an extent out of all proportion to that which occurs among the latter? When we find these very differences occurring in a marked degree between the poor which

inhabit the large cities of England, and those which reside in our Scottish towns, our opinion of privation being a source of fever is strongly confirmed. The English pauper is in many respects placed under circumstances similar to his brethren of the north, differing, however, widely, in the extent of destitution and the prevalence of fever. The poor of both parts of Her Majesty's dominions are exposed to the influence of malaria, originating from the same sources: they are alike crowded together in small, ill-furnished, and badly ventilated apartments; they are of the same filthy and intemperate habits. The only difference in their condition is, that those who have the good fortune to live south of the Tweed are protected from the awful destitution which exists among the poor who live on the north side of that river. In Scotland the vast majority of our poor are wholly unprovided for by parochial relief. Those to whom this charity is extended receive a trifling sum, about two shillings per week—a sum totally inadequate to their maintenance; whereas, in England, three times this amount is given. In England the average expense for maintaining the poor is still five shillings and tenpence per head on the population. Previous to the late shameful reduction it was much larger. It is, however, nearly five times as much as that which is levied in Scotland. It is less than sixteen-pence. Let us examine, then, the extent to which fever attacks the poor of these two countries.

In Manchester the cases of fever admitted to the hospital in 1836 amounted to 780, or one to every 292 of the population. In Leeds the number treated in the fever hospital was 274, or one to 450 of the inhabitants. In Newcastle and Gateshead the number admitted to the fever hospital is 39 annually, or one to 1485 of the population. In Carlisle, where fever was epidemic in 1831, one out of every 121 of the population was admitted to the infirmary; previous to this year 63 cases was the average number admitted. In Sunderland, with a population of fifty thousand, only 17 cases of fever were taken to the hospital in each year, during 1836-37-38. In Oxford, fever occurs in the proportion of one to every 3200 of the inhabitants. Liverpool, in 1836, presented to the hospitals 1700 cases of fever, or one for every 112 of the population. In

* Vid. Brit. and For. Med. Review, No. xxi.

London, during the epidemic of 1838, one out of every 67 of the population was seized with fever. The population of the four districts of this city* where the fever principally raged, amounts to 253,784: of this number only 6097 were seized with fever, or one out of every 42.

Let us compare these numbers with Glasgow. In 1836 the admissions to the fever hospitals amounted to 3125, or one out of every 78 of the inhabitants; one out of every 22 of the inhabitants was seized. In 1837 there occurred 21,800 cases of fever out of a population of 244,000, or one out of every 11 of the inhabitants. In Edinburgh and Dundee we have seen that the inhabitants suffered to a proportionate degree with the citizens of Glasgow.

From these facts we have the painful conclusion forced upon us, that the poor inhabitants of Scotland are subjected to the inroads of fever to an extent totally unparalleled in England, where the destitute obtain more adequate assistance. It may be argued that the prevalence of fever among the poor of Scotland cannot be considered as any proof of poverty being a source of fever, so long as the same disease attacks, though to a less extent, the English poor, who do not suffer the same privation which is experienced in Scotland. It has been said that if fever arise from poverty, it cannot prevail where the evil does not exist. In England, therefore, where the poor have a provision made to protect them from destitution, there should be no fever; but in England fever does prevail to a very great extent—*ergo*, poverty cannot be said to be the source from which it originates. Those who adopt this mode of reasoning forget that the destitution in Scotland and England is only comparatively different: they overlook the important fact that the poor of these two countries differ in the extent of their privations. The English pauper is only half provided for; whilst the poor Scotchman is left almost wholly destitute. Now we find, from the most incontrovertible authority, that the prevalence of fever in England and Scotland also differs in extent in the same ratio in which the state of destitution is different. Both countries will ere

long, however, be reduced to the same level in these respects, if it be in the power of the Poor Law Commissioners to effect it. We must not overlook the powerful influence which contagion exercises in generating and propagating fever. We should also take into consideration that, in England, many causes exist which increase the virulence of contagion, and assist its diffusion, such as bad ventilation, &c. This special pleading can have little effect in opposing the conclusion that poverty is not only an attendant on fever, but a source of the disease, supported as this opinion is by the mass of facts adduced from all quarters.

To conclude, we have seen, then, in the first place, that contagion is, beyond all doubt, a source of typhus fever: the evidence on which this inference rests is of the most direct nature.

2. We have examined the facts from which some medical men attempted to prove the malarious origin of fever. We have found, in the first place, that there is an insufficiency of facts to warrant this doctrine; in the second place, that the facts adduced do not prove the malarious origin of fever, but merely that fever generally prevails among the habitations of the poor, who do not receive adequate nourishment; thirdly, we have found many powerful facts, which completely oppose the existence of any such relation between effluvia and typhus as that of cause and effect.

3. We find an immense collection of facts to support the opinion, that privation is not merely an attendant on typhus, but is frequently (though by no means always) the very source from which the disease is originated. I wish these conclusions, however, to be viewed in their proper light—to be considered as the inferences which the facts that we possess on the subject authorize us to deduce; consequently they are mere approximations to the truth. Future investigations may reveal many circumstances by which they may either be still further confined, or completely overthrown. I would again repeat that I view them as correct deductions from the facts furnished by the present state of our knowledge of the phenomena attending the origin and propagation of typhus fever. I fully admit that bad ventilation and filth are great evils, and ought to be removed; they are doubtless active

* St. George the Martyr, Bethnal Green, White-chapel, and Lambeth.

agents in the propagation of contagion; but let the influence which they exercise be viewed in its proper light. I would strongly urge the removal of those beds of filth and nastiness which disgrace our cities, and mock our pretensions to civilization and humanity. I would warmly advocate the construction of sewers, the widening of streets, and the formation of places for recreation in the centre of these crowded cities. Let the external circumstances of the poor be made as comfortable as possible. Let measures be adopted to allow "the entrance of the light of the sun into their dark and gloomy recesses," and the sweet and invigorating breath of heaven "into their foul and reeking habitations." If such means were employed, I doubt not but that we would have less reason to lament over the ravages of fever, less cause to mourn over those horrid scenes of destitution and disease which we have had lately under consideration. But the advocates for the malarious origin of typhus would stop here. They contend that by proper ventilation, by the formation of sewers, and removal of filth, fever could be totally destroyed. At page 14 of the report "of the Sanatory," &c. to which allusion has been made in a previous part of this essay, they tell us "that by proper sanitary police regulations . . . the typhoid fevers of London and other places might be made to disappear."

This doctrine is fraught with the most dangerous consequences to the interests of society. We find it adopted by the Poor Law Commissioners, who recommend the principle to be put into immediate practice, in order to stop the ravages of fever. These gentlemen and their friends strongly maintained that nothing else is necessary to obtain this much to be desired object. Never were men more miserably deceived; and would that this were the only mischief which will arise from the practical adoption of these views. The eyes of the public will not be opened to the deception until thousands of victims shall have fallen a sacrifice to the very disease with which these men are not only tampering, but actually fostering. They might as well think to destroy the thousand ills to which suffering humanity is liable, as to imagine they can annihilate fever by merely removing the alleged causes of malaria.

Though they ventilate and clean the dwellings of the poor till they attain to the highest state of perfection, yet fever will still continue to rage; nor will it cease its devastations until you feed the poor—until you give them sufficient stamina to withstand its influence. Typhus originates from causes within the human body, not from any exterior source. To attempt the removal of the disease by destroying the external circumstances with which the poor are surrounded, and, at the same time, to allow the internal cause either to remain unnoticed or become aggravated, is as unwise as it is absurd. It is really painful to witness the endeavours of the Poor Law Commissioners to reduce the dietary of the poor to the very lowest ebb consistent with the maintenance of vitality. They seem to act on the principle of the man who managed to reduce the food of his horse to a straw a day; but, perhaps, would not regret with the man the result of this wicked economy. It is true, indeed, that the funeral expenses might give rise to a pang in the hearts of the *junto* of Somerset House.

These advocates of pork wate, and gruel, in their ardour to have filth and the other alleged causes of fever removed, as the only means necessary to ensure health and happiness to the poor, completely overlook the fact that filth and nastiness are the effects of poverty; they are its universal concomitants; and so long as privation continues, these conditions will exist. It is great folly, to say the least of it, to endeavour to remove the effects, and to aggravate the cause. These wisacres, while they are earnest in their recommendations to clean the poor man's dwelling, seem exceedingly anxious that his inside should not be defiled with alimentary matters. They forget that human beings are not chameleons, and require something more substantial to maintain health and prevent disease, than air, however pure.

Would that the eyes of government were opened to the absurdity, or, I should rather say, the wickedness of the principles of economy advocated by the Poor Law Commissioners. The economy which they advocate is lavish expenditure. Let the poor receive better and more adequate nourishment, and we will have not only less fever, but less filth and nastiness to remove.

Be not content with the removal of the latter only. Destroy both it and the privation which exists along with it. Let not only the dwellings of the poor be well ventilated, and cleansed from the filth by which they are surrounded, but let the inmates receive adequate nutriment. Both measures are absolutely necessary to obtain the object in view, viz. the removal or mitigation of fever. If the poor were well fed, we might have more prospect of "proper sanatory police regulations" effecting some good in the extinction of fever. Then we might expect that this dreadful scourge which infests our large manufacturing towns would be stayed in its dreadful career of devastation. By thus enabling the poor to withstand its deadly influence, we might anticipate a stop being put to the progress of this enemy of human life, which is careering with giant strides over the length and breadth of our land, filling with wailings and misery the habitations, not only of the poor, but of every class of society. "Could the public money," observes an eloquent writer, "be appropriated to a more suitable purpose than the prevention of disease? The preservation of the public health is economy in every sense. It not only saves money, but it makes it. It substitutes men for children—productive for unproductive labours. It supplies a country with its best riches, and its cheapest defence—the arm strong to labour and to fight."

ON THE SYPHILITIC DISEASES OF THE LUNG.

By WILLIAM MUNK, M.D.

Physician to the Tower Hamlets Dispensary.

[For the Medical Gazette.]

FROM the period at which syphilis is generally thought to have originated, or at any rate from that when it first forcibly attracted the attention of the public and of the profession, up to the latter end of the eighteenth century, a space of more than three hundred years, the study of its natural history, more particularly of its progress and of its tendencies under peculiar modifying influences, was but little regarded; writers on the subject giving themselves more to speculation than to

observation: the few, indeed, who pursued the latter and only legitimate course, being overlooked and forgotten amidst the extensive and overwhelming literature which had year after year been accumulating on this subject.

Towards the end of the period above specified—in the year, that is to say, of 1784—Hunter gave to the world his great and important treatise on the Venereal Disease; a work which, to use the words of a distinguished living writer, "poured a flood of light not only on the natural history of the disease but also on its pathology and treatment."

The merits of this work were so evident that it became at once, and as it were by acclamation, the guide for students and practitioners—the text alike of lecturers and writers. The latter did little more than follow our yet further illustrate the various subjects discussed by Hunter; but few presuming to enlarge the boundary on which he trod. It seemed, indeed, as though the master-mind had grappled with the whole subject: had embraced within his comprehensive grasp all possible ramifications of the disease; had solved the most difficult problems in the inquiry, and had left only to his successors the working out of some secondary points, which time and more important topics had allowed him but briefly to shadow forth.

Any formal discussion on the peculiar merits of this important work would now, indeed, be superfluous, public opinion having long since, and most justly, awarded to it the highest place among the modern contributions to our art. Hunter studied the subject practically: he carefully observed the phenomena that came before him, reasoned cautiously upon them, and then committed to writing and to the world his matured conclusions concerning the disease. Further than this he did not go. The work was the pure result of his own observations and reflection, unaided by the facts or doctrines of predecessors or contemporaries.

Hunter was a surgeon, and in his day the demarcation between surgery and physic was better comprehended, and less infringed, than at the present time. His opportunities consequently of observing the disease must have had reference chiefly to it when occurring

in those situations the morbid affections of which have by common consent, and long-established usage, been consigned to the surgeon's care. The diseases of the general surface, of the orifices of the body, as far as these are within the reach of the senses of sight and touch, of the bones, &c., are those with which the surgeon is chiefly busied; and syphilis, as affecting these parts, has been well described by Hunter. But the disease may fix itself upon other parts—upon parts not mentioned by Hunter or his followers; upon parts the diseases of which fall properly to the physician's province.

These circumstances will in some respects account for the late very general neglect of many internal syphilitic affections, the existence of which was fully recognized by the older physicians, and has either specially or incidentally been treated of in their writings. Perhaps the most evident, certainly not the least important, of these, are the syphilitic affections of the lung, a subject to which my attention was first directed, when a student in Holland, by the writings of my esteemed friend Professor Schroeder van der Kolk, of Utrecht*. It is to Dr. Graves†, of Dublin, however, that the profession in this country stand indebted for once more directing attention to this really important subject. In one of his clinical lectures published in 1835, he makes some highly interesting and practical observations on the disease, acknowledges that from the late Mr. Hewson he derived his first information concerning it, and expresses his surprise that the subject should for so long a period have been overlooked or neglected.

The records of our profession abound, however, with illustrations of pulmonary disease, the existence of which was attributed, and as it seems justly, to the contamination of the system by syphilis. Morton devotes the seventh chapter of his well-known *Phthisiologia* to the special consideration of *phthisis à lue venerea orta*, and concludes his observations with the detail of a well-marked instance of the disease cured by mercury and sarsaparilla. *Etiam verum est* (says he) *et in praxi*

non raro observandum venit, vere pulmonalem phthisin a mera sanguinis et humorum alteratione lue venerea facta originem suam ducere. Neque quidem mirum est cum tota humorum massa tam evidenter ab hujus morbi fermento alteretur et in statum colliquativum reducatur (quod a tumoribus malignis gonorrhœis et ulceribus hunc morbum usitato comitantibus apparet satis) si etiam hujusmodi tumores atque ulcera venerea, aliquando in spongioso et molli pulmonum parenchymate accedant unde phthisin vere pulmonalem insequi necesse est. Ego equidem potius mirari soleo luem veneream saltem chronicam seu malè curatam unquam sine pulmonum ulcere et phthisi inde nata reperiri.

Sauvage*, partly on the authority of Morton, and in part from his own observation, admits, as the eighth species of secondary phthisis, phthisis syphilitica; a form of the disease which has been received likewise into the nosological systems of Cullen and Macbride.

Portalf, in the tenth section of his work, treats at length of this disease, and the late learned Dr. James Sims, in his observations on epidemic disorders, has the following remarks. The kind of this disorder (phthisis) most commonly met with here, as well during this as other years, was such as took its origin from a bad crisis of the blood, rather than from any inflammation of the lungs. In many cases this seemed to be derived from a previous gonorrhœa, of which the person thought himself completely cured a year or two before. I would therefore advise every physician, when called to a tabid patient whose manner of life may have thrown him in the way of such disorder, carefully to inquire whether they ever had any venereal complaint, as it is never to be disregarded in the prescription. This phthisis, though it did not differ materially in its symptoms from those to be described hereafter, yet required a very different treatment, mercury being the sole refuge, which never failed performing a cure when taken before the lungs had inflamed and suppurated‡.

referred to, many of whom have, in corroboration of their general remarks, adduced instances of the disease, individual cases will be found recorded in the *Acta Medicorum Berolinensium**, by Hoffman†, Morgagni‡, Tode§, Schwartz||, Meza¶, Saucerotte**, and others. These names will, it is hoped, suffice to prove that, as far as reputable authorities and a tolerable amount of antiquity are concerned, the idea of syphilis attacking the pulmonary tissues, far from being a newly-broached and novel doctrine, is in truth to be regarded as perfectly orthodox medical belief.

By every author above referred to, Dr. Graves alone excepted, the pulmonary affection induced by syphilis has in its nature been regarded as akin to, if not identical with, phthisis; whence the name *phthisis venerea vel syphilitica*, by which it has invariably been designated. Since the use, however, of the word *phthisis* has been confined within narrower limits, and has been regarded as identical with pulmonary tubercle, and these as terms mutually convertible, the propriety of such a term as *syphilitic phthisis* has indeed become somewhat doubtful. In the present day there exists a pretty general disbelief of any peculiar power possessed by syphilis of giving rise to tubercle, and as modern researches have satisfactorily shown that scrofulous or tubercular cachexia is an inviolable, and indeed necessary precursor of tubercular deposits, it is evident that tubercle, if at all, can under two circumstances only be regarded as venereal. These are, either when syphilis develops this peculiar cachectic state, and thus by its agency, and therefore indirectly, generates tubercle, or when it occurs in an individual already cachectic or tuberculated, pursues its course with, and materially modifies these conditions.

In reference to the former of these it may be objected that it is very doubtful whether syphilis has a greater tendency than any other severe disease materially disturbing the constitution, to induce a scrofulous state, and supposing that it does so, whether the resulting condition differs in any material respect, as regards nature or treatment, from the more commonly observed cases. Regarding the latter it may be urged that the accidental co-existence of syphilis and tubercle, or of its prelude, scrofulous cachexia, particularly when the last-named conditions have had a priority of being, will not justify our formally distinguishing and separating such cases from those of every-day occurrence, unless it be first shown that the cachectic state, and ensuing tuberculization, be materially altered in their course, symptoms, or essential treatment, by the co-existent contamination.

These, then, are but a scattering of the difficulties which surround us when we go to admit the existence of such a disease as *syphilitic phthisis*.

For the satisfactory determination of the question, we at present possess no sufficient evidence. The different subjects bearing upon it have either been wholly neglected or but theoretically discussed, and our information consequently is both vague and limited. First it would be necessary to define the meaning to be attached to the term *syphilitic phthisis*; and then to work out the investigation by an extended series of well-observed and carefully-collected facts. As the object of this paper is the illustration of those pulmonary diseases which result directly and immediately from syphilis, *syphilitic phthisis*, the latter being used as above explained, cannot fall within the scope of our remarks. The only reason, therefore, in view, in this discussion, is that all the recorded examples of *syphilitic pulmonary disease*—examples from which indeed I shall have in part to draw my own conclusions—are incorrectly, according to my view of the case, chronicized as *phthisis*.

What then, it will be asked, is the intimate nature of the morbid action set up in the lungs by a *syphilitic taint of system*, if it be not *tuberculization*? My own observations, and the careful review of recorded cases, justify

me, I think, in affirming, that inflammation is the action, and either the bronchial mucous membrane, or the pulmonary parenchyma, the immediate seat of that action: in other words, that syphilis displays itself in the lung under the varied forms of bronchitis, pneumonia, or bronchopneumonia. I am not prepared to say, observes Dr. Graves, which of the pulmonary tissues is most usually attacked by the venereal poison, but I believe that it chiefly tends to the bronchial mucous membrane, although, like other animal poisons, *e. g.* those of measles and scarlatina, it may also occasionally produce pneumonia.

The remarks of Dr. Graves having reference to the chronic form of syphilitic bronchitis are amply borne out by Dr. Stokes, who by his account of the acute form of the same disease has made a most important addition to our previous information. His remarks being extremely valuable I shall quote them at length. With respect to the bronchial system, says he, we may observe the disease as an acute or more chronic affection. In the first instance it is analogous to the bronchial irritations of the exanthemata, of which I have seen a few interesting examples, while in the second there is a chronic irritation, which, when combined with the syphilitic hectic, and with peripneumonia of the chest, closely resembles true pulmonary phthisis. In the first of these cases I have observed, that after a period from the first contamination, the duration of which has not been determined, the patient falls into a feverish state, and presents the symptoms and signs of an irritation of the bronchial membrane. These having continued for a few days, a copious eruption of a brownish red colour makes its appearance on the skin, and the internal affection either altogether subsides or becomes singularly lessened. Here we see the bronchial membrane taking on an action which is peculiar, and very different from its ordinary irritations. There is an inflammation only analogous to that of the exanthemata, and no doubt can exist that it is connected with the syphilitic poison. My friend Dr. Byrne, whose situation as medical officer of the Lock Hospital gives him the greatest opportunities of observation,

informs me that he has in many instances seen patients who had been formerly diseased, and who had come into hospital either for new sores or for gonorrhœa, attacked with intense bronchitis and fever. This attack would come on suddenly, and the distress was so great that bleeding had to be performed: the effect of which was, that soon after, a copious eruption, often combining the lichenous and squamous forms, made its appearance, with complete relief to the chest. In some of these patients on the day before the eruption the stethoscopic signs had been those of the most intense mucous irritation, and yet when the skin disease appeared the respiration became either perfectly pure, or only mixed with an occasional rhonchus in the large tubes. The same gentleman has observed the reverse of this; as, when a syphilitic eruption has been repressed, the bronchial membrane has become much engaged, and the patient affected with general febrile symptoms. These phenomena subsided after bleeding and mild diaphoretics, which had the effect of restoring the cutaneous eruption. Here we have an additional evidence in favour of the analogy between syphilitic bronchitis and that of the exanthemata.

The deservedly high position of Dr. Graves and Dr. Stokes, as authorities on all matters connected with thoracic pathology, renders my feeble testimony upon this point altogether superfluous; and their recorded statements are, it seems to me, amply sufficient indisputably to establish the existence of such a disease as syphilitic bronchitis, acute as well as chronic.

The chronic form of the complaint is in all respects the most interesting and the most important. It is the most usual form under which syphilitic bronchitis presents itself; and, when combined with some other morbid conditions often consequent upon the existence of the syphilitic poison in the system, is exceedingly likely to be mistaken for true phthisis, and thus to lead to an unnecessarily bad prognosis, and to be both incorrectly and inefficiently treated.

[To be continued.]

SOME PHYSIOLOGICAL REFLECTIONS
ON
THE NATURE AND TREATMENT OF
ANGINA PECTORIS,
AND OF ANALOGOUS STATES.

By T. WILKINSON KING,

Lecturer on Pathology at Guy's Hospital.

[For the Medical Gazette.]

Introduction. Physiology of violent circulation—lymphatic system. Influence of repletions. Physical changes in the heart which attend advancing years—the like in the valves, surfaces of contact, and perforations. Slight disorders approaching to angina

DISEASES, like the natural functions, may be physical, nervous, or humoral, or they may involve all these circumstances. It is our object here to illustrate the physical part of the general doctrine of cardiac affections still more than to show how these doctrines are to be applied in a particular set of cases. Without, therefore, aiming at too great precision, and without supposing that, here and there, we may not be altogether wrong, we desire to offer these opinions as in the main available, and even essential, to the explanation of most thoracic diseases. We venture to conclude that there are no satisfactory explanations of the anginal affections amongst authors. Perhaps the most complete history of angina is to be found in the paper of Dr. Forbes, in the *Cyclopædia of Practical Medicine*. Dr. Forbes admits the basis of our opinions, and he quotes some writers who seem still more to favour them; but those who may refer to the article in question will hardly feel that the subject does not require a more distinct exposition. It is hoped the following views may ultimately lead to this.

We shall regard the anginal attacks as of varied character, and endeavour to show on what the different features depend; premising only that there are probably many more facts than those we mention which are to be explained in a similar manner; and, again, others which need a different train of illustration.

Our first object will be to consider the physiological state of the circulation at the ordinary onset of the first attack.

Walking, or any continued exercise, steadily accelerates the circulation. The muscles compress, distort, and impede the arteries, and empty the veins, generally facilitating the capillary circulation. The right side of the heart contracts on a larger amount of blood. The expansions of the chest in respiration, and especially the inferior lobes of the lungs, are extended to a much greater degree than is commonly thought, under slowly but steadily increasing efforts; while it also becomes more frequent. By the same gradual changes the left side of the heart is adapted to a fuller circulation: it is dilated more freely, and contracts more powerfully. Doubtless, too, the aorta attains an acmé of expansion under the increased impulses. All men are familiar enough with the main fact here expressed, that the fullest freedom of the chest is only well attained by slowly increasing exertion. It is what trainers call second wind: and cannot be suddenly attained, nor can it very rapidly cease. Its perfection is scarcely to be looked for beyond the freshness of manhood; and, without doubt, we ought to expect that this exaggerated physical state of the circulation is in danger of surpassing the bounds of health. We suppose, moreover, that the manifestations should be both sudden and severe, in the event of any part failing in its office.

Other physical circumstances are more or less directly or frequently concerned with the above. The influence of pressure on the lymphatics is to empty them also rapidly towards the heart; but this consideration applies most particularly to the lacteals, supposing them to be engaged, as after a meal; although it is doubtless true, that the more active distribution of blood over the whole body, when in exercise, is a means of retarding the assimilative functions of the bowels.

In addition, a full abdomen adds to the accumulation of blood in the chest, and also obstructs the lungs; and in a measure impedes the filling of the left heart. We shall again find occasion to introduce the occasional sources of mechanical difficulties in the circulation.

There seems to be another necessary consideration in relation to the healthy condition of the heart in full play. We refer to the orifices and their valves. In the fourth volume of the

Guy's Hospital Reports, the valves were shewn to possess more or less of surplus curtain—some membrane to spare in the ordinary easy action of the organ—constituting pretty defined and extensive surfaces of contact: and with respect to these parts in the healthy state, it is necessary to remark that certain exertions are required to bring them into operation as parts of their proper valves; and that their occasional use is essential to their due nourishment and strength. It is by the healthy yielding of their several orifices that the valves are enabled to exercise the full breadth of their curtains, and without this exercise they fall into diseased and inefficient states, of which we shall speak in their proper place. The reader will not be at a loss to conclude that we propose to date the commencement of common angina from the mere physical state belonging to what is called second wind.

In the next place, however, we have necessarily to reflect upon the peculiar changes which the heart undergoes as the period of life approaches at which anginal attacks may arise. M. Bizot has proved numerically that in health the capacity and thickness of the left ventricle increases steadily from manhood upwards; and also that the general breadth of the heart bears a pretty definite relation to that of the shoulders or chest; and we suppose we may conclude that, as age advances, the elevation of the shoulders and increased expanse of chest, by facilitating the access of blood to the left ventricle, are not without their influence on the dilatation of that cavity, while the growing difficulties in the arterial circulation call for the augmenting force and nutrition of the ventricular parietes. The feebler and slower circulation may still require other considerations to account for them completely. We may remark, too, of the rise of the shoulders and corresponding changes, that this is not all the result of senile emphysema, and it is by no means necessarily an impediment to the transmission of blood from the right to the left heart. The dilatation of the heart, blood-vessels, and capillaries, as well as of air-cells, may bear a pretty exact proportion to the expansion of the chest (the inspiratory muscles having but few and weak antagonists), and to many other correlative changes.

It is not at all apparent that hypertrophy, with an increased cavity, is indicative of augmented power in the ventricle as a whole: the two circumstances, simply, are mainly indications of delay and accumulation; yet in one hour such a ventricle may act too freely on a moderate quantity, or be burthened with an excessive fulness. Now the great orifices of the heart evince a similar tendency to expand with age; and under the most favourable circumstances the valve-curtains seem to extend themselves almost commensurately; but this is too uncommon: for being so delicate and so constantly and unequally exercised, they are, of all the parts of the heart, most prone to fall into disease, and the commonest changes are those of thickening and contraction. Two more changes we shall also speak of in the valves, which are truly morbid, but which, like the last, often seem of small importance in the easy states of the circulation. The surfaces of contact, when perhaps a too uniform state of the circulation may have been long preserved, are liable to two kinds of disorder, which are to be found separately, or commingled in many degrees. Portions of the curtains, through disuse, become attenuated and perforated, or altogether lost; and, again, the parts employed are liable, where most drawn upon, or when most intimately pressed or rubbed together, to become thickened, and even contracted.

At present we have no occasion to dwell more at length on these often trifling alterations; but, with respect to their occasional importance, we would remark, that their influence is most considerable where the truest and strongest propulsion is demanded; namely, in the left side of the heart; and here, too, their features are most strongly marked and fully developed; and, most of all, in the aorta.

Perforations near the free edges of the aortic valves are very common after thirty years of age, and they are very easily overlooked. Before they can be brought into mischievous influence (having been induced by a more or less easy life and circulation), the valves must be unusually extended by a combination of repletion and exertion, and probably, in the common case, by hypertrophy of the left ventricle also. Gradual contraction of a curtain must

operate in a similar manner, leaving it liable to become inefficient.

It is not necessary for us to describe all the states of the circulation which concur with different anginal affections. These can only be treated of in connection with their specific symptoms. The strong heart, the atrophied organ, and that which is materially altered in its relative proportions, offer very distinct cases. We know how variously the heart may fail with advancing life, in its substance, its cavities, its orifices, or its valves; and even in its dependence on other organs.

Many changes may thus affect the heart along with the muscular system generally; and it is ever to be remembered, that, in order to approach a diagnosis of the state of the heart, as to its mass, texture, &c. it will be very available to consider the age, sex, and constitution of the patient, in reference to the muscular system in particular, as well as generally.

The sudden affections of wasted or enfeebled hearts constitute a distinct set of anginal disorders; but in every kind of case we must contrast together or study the relations between the distension and resistance, the size of the cavity, and its power of contracting, and also between the extent of the orifices and the states of their valves, before we can estimate the share which any part takes in the production of symptoms or of death.

It is not to be forgotten, as one useful part of the introduction to the study of angina, that there are some pretty sudden and severe affections which may be induced in younger and more healthy subjects by causes like those of angina. These may be regarded as states (shall we say?) short of angina. Palpitation, or an excessively rapid pulse, or even an irregular pulse, are common effects of exertion. In undue or severe degrees these must be referred to weakness and dilatation of the heart, or a part of it, as we shall see hereafter. The small frequent pulse may well be accounted for by an over-full left ventricle, weak, overburthened, and having lost all the easy relation which existed between its size and form, and the aperture of egress.

The small and less rapid pulse belongs to the defective supply to the left ventricle from any cause. In either of the foregoing instances the pulse

may also be irregular. We attribute the intermitting pulse of the more healthy to a certain disproportionate hypertrophy of the left ventricle.

The side-ache of exertion, repletion, or agitation, may illustrate the states under consideration. We conceive they belong to congestions, as in the spleen or liver. When brought on by running, the pain is singularly under control by rest or pressure, or even perhaps full breathing.

Some dyspnoea from exercise, under many circumstances, may be considered natural, but its unhealthy degrees are frequent enough. An additional quantity of blood passing on to the lungs produces the increased *besoin de respirer*, whilst undue fulness of these (and still more at times of the bronchial linings) renders the inspiratory effort laborious. Delay in the left heart, or excessive propulsion from the right, may aggravate the mischief. Bronchitis and asthma tend to diminish the supply of blood to the left heart, and render its actions almost too easy; and so also may a very simple disposition to dyspnoea in exercise, which also, by inclining to rest, leaves the left heart too little engaged and nourished. On the other hand, in some thoracic diseases, gentle exercise, in the intervals of repletions, accelerates the general circulation and secretions, and so relieves the lungs and stimulates the left heart, which, but for this, would become an additional cause of delay.

We have not adverted to the instances of casual syncope from exertion, yet it must appear that these will serve to illustrate the less mixed cases of fatal fainting, and the first are not to be omitted in a review of the slight and transitory states, by the contemplation of which the gravest conditions may be the more easily explained. The faintings of delicate persons from slight causes, or of those which are stronger from somewhat greater disturbances, seem all to depend on this—that the right heart receives too little blood. The veins are not full enough, and the general relaxation of muscles (whether from defective blood or nervous supply) leaves the veins to yield to the effects of gravitation.

In this place it should also be remarked, that perspiration and the general freedom of secretions, as well as of capillary circulation, and perhaps even the ful-

ness of superficial* and other veins when greatly excited, indicate the nature as well as the need of relief, and in a manner are near approximations to disease or distress.

[To be continued.]

ON THE OPERATION FOR TALIPES.

To the Editor of the Medical Gazette.

SIR,

IN the communication you did me the favour to insert in your number of the 11th of December last, I promised you a report of some cases, illustrative of a new operation for the cure of a certain variety of talipes, for which the Stromeyerian operation was inapplicable. I shall now endeavour to fulfil my promise, although my avocations compel me to do so very briefly. Besides its reference to those cases of talipes, it is moreover interesting as calculated to meliorate many other infirmities arising from total paralysis, or diminished power, of certain classes of muscles.

In the month of June 1840, I had my attention directed to this subject by observing the peculiar gait of a gentleman who was passing along the street. Although I neither knew nor spoke to the individual, I was struck with the manner in which he walked, and took more notice of it from the circumstance of being at the time much engaged in the practice of the Stromeyerian operation for the cure of club-foot. That operation consists essentially in the division of the tendons of muscles, which act too energetically, and extending them, before the lymph which is thrown out to cement the divided extremities together has become consolidated: so that, in the end, there is a new portion actually implanted between the divided extremities of the originally contracted tendon. That this is not a speculative idea I can prove by specimens in my possession. I observed that in the variety of the malformation referred to—evidently caused by paralysis—there was no morbid tension; but, on the contrary, a morbid relaxation. The idea occurred to me, that if a portion of the tendon were cut out, and the divided extremities made to reunite, by being kept in contact during

the healing process, it would at least improve the flapping condition of the weak member, and by retaining it in a state of greater tension, might produce a tendency to contraction in the paralysed muscles. On my return home I explained my views to my intelligent friend and patient, Mr. Rhind, Surgeon, Edinburgh, who was then under my care for the cure of congenital talipes varus of the worst degree in both feet. I told him that the propriety of the operation was so strongly impressed on my mind that I was determined to adopt it the first time a case of the kind referred to came under my care. He expressed himself much pleased, and considered it a fortunate idea. It was not long ere I had an opportunity of testing the value of my proposed new mode of practice in the case of Miss —, which I shall now detail.

CASE I.—Miss —, æt. six years, has been deprived of the use of the left leg by a paralytic stroke. She has undergone a variety of treatment under some of the first medical gentlemen of this town: but, for the last two years, has been given up as a hopeless case. Her present condition is this: the left leg is perfectly powerless, dangling by the side of her crutch, without reaching the ground, and is much colder than is natural: the foot assuming the appearance of a slight degree of varus, so that it would, if brought to the ground, rest on its outer edge, the toes inclined a little inwards, and the heel slightly elevated. On the 30th of June, 1840, assisted by Mr. Rhind, my son, and one of my apprentices, Mr. Pacey, I made a longitudinal incision along the course of the peroneus tertius, which I elevated, and excised a portion of it, to the extent of three-sixteenths of an inch. I then closed the wound with plaster, and applied splints and bandages, so as to approximate the divided ends, and maintain them in contact.

2nd day.—Has been free from complaint.

4th.—Removed the plaster, and, after bathing the foot, again applied plaster and bandaging as before. Care has been taken, during the dressing, not to extend the foot so as to separate the recently approximated extremities of the divided tendon.

6th.—All going on well; and now feels the foot and leg quite warm.

* The blood-horse illustrates this fact.

7th.—Has entire command of the leg, and so much strength in the foot, that I requested her to take hold of my hand, and try if she could use her limb, when, to the surprise of all present, she was able to walk across the floor of my surgery.

10th.—In the presence of my talented friend, Dr. J. L. Bardsley, and others, she actually walked across the room and back again without any assistance whatever,—a fact which equally astonished and delighted him and all present. In twenty days she was enabled to walk about in a laced-up boot: and in a week more to throw her crutches aside entirely. She has continued well and strong ever since. Besides the operation nothing else was done in this case, excepting the use of a stimulating liniment, which she had employed before without the least benefit.

CASE II.—Miss —, æt. 10, has been suffering from an attack of valgus of the right foot for the last six years; the malleolus internus nearly resting upon the ground when supporting the weight of the body on this leg; not from contraction of any muscles, but from a paralytic state of the tibialis posticus and flexor longus pollicis pedis of the right foot. With the same assistance as in the former case, I excised nearly a quarter of an inch of the tendons of the tibialis posticus and of the flexor longus pollicis pedis, and dressed and bandaged as before, so as to keep the divided extremities in contact. All went on perfectly well, and from the day the operation was performed, the patient said the foot felt warm, although previously the foot and leg were constantly cold. In three weeks she could walk quite straight: the foot and ankle being maintained in their proper relative position.

CASE III.—The next case was Mrs. —, æt. fifty, who had suffered from varus of the right foot from infancy, arising chiefly from a paralytic state of the peronæus longus and brevis. On the 6th of July, 1840, I excised three-eighths of an inch of these tendons, above the malleol. extern., closed the wound with plaster, and bandaged it so as to keep the ends of the divided tendon as much approximated as possible.

2nd day.—Quite free from constitutional irritation, and all complaints.

3d.—Makes no complaints; says she feels the foot much warmer, and can

now move the toes for the first time in her life. Every thing went on in the most satisfactory manner in this case: and in twenty-one days she was enabled to put on a laced-up boot, provided with a steel support, which enabled her to walk about with much more comfort than formerly. From want of attention the improvement did not continue so manifest as at first. The experience I have now had leads me to believe that this may be partly attributed to the circumstance of the tendo-achillis being slightly contracted. Had I such a case to operate upon now, I would divide and lengthen the tendo-achillis, whilst I would take a portion from, and thus shorten, the other tendons referred to.

CASE IV.—Master Gresty, æt. 6½ years, has had talipes valgus since one year old, arising from absolute paralysis of gastrocnemii and other muscles on the back of the leg; so that there is not only total inability of extending the foot, but such relaxation of all the extensor muscles, as to allow the foot to be pressed upwards until it touches the front of the leg. On the 4th of Sept. I excised three-eighths of an inch of the tendo-achillis.

3d day.—All going on well.

5th.—Makes no complaint: wound nearly closed, and very little matter discharged.

7th.—All going on well, and still great warmth of foot and leg, which has increased since the operation, although there is no pain or inflammation to account for it.

10th.—Wound nearly closed; tendon so firmly united as to resist any attempt at pressing the foot upwards, excepting a little beyond a right angle with the leg: and has now power of flexing and extending the foot freely: showing that the paralytic state of the extensor muscles is completely overcome. At three weeks after the operation this patient fell and injured the leg, so as to cause inflammation and suppuration around the newly formed cicatrix, which retarded his recovery. After this had subsided, with the use of a stimulating embrocation, this patient regained the use of his extremity, so that he could in three months after the operation walk with ease; flexing and extending the foot freely, and capable of supporting the foot and leg in its proper relative position. Before the operation any attempt at walking was attended with

great awkwardness; the leg being tossed forward, the toes turned very much outwards, and the inner ankle approximating the ground.

CASE V.—Master B—, æt. 12½ years, from a paralytic seizure or accident, they cannot tell which, has been much in the same state as the last patient, for about a year. In October 1840, I excised five-eighths of an inch of the tendo-achillis, dressed and bandaged as usual.

3d day.—All going on satisfactorily.

4th.—Makes no complaint; wound nearly closed, and very little matter effused; dressed and bandaged as at first.

6th.—Wound almost entirely closed, and has now the power of flexing and extending the foot freely, indicating the reunion of the tendo-achillis as well as restoration of retractile power. Foot and leg still kept bandaged in the same manner as at first.

8th.—All going on most satisfactorily.

In two months put on a laced-up boot, with which he walked freely; has continued without complaint, and can now walk nearly as well as if he had never been so afflicted.

CASE VI.—Master Moss, æt. 10 years, has right leg quite useless from a paralytic seizure in infancy. The leg not only powerless, but also cold and withered, being about half the size of the other one. The knee bent to an angle of 45°; the foot turned outwards, and can be easily pressed up against the tibia, showing the extreme want of tone of the gastrocnemius and tibialis posticus. I excised three-eighths of an inch of tendo-achillis, and about as much of tibialis posticus; dressed and bandaged as usual. All has gone on well; and he is provided with a high-soled boot, to compensate for the shortness of his leg. He can now walk without a crutch, merely requiring the assistance of a stick. This leg is much grown, and greatly warmer than before the operation; indeed, he is altogether stronger.

CASE VII.—Miss —, æt. 10 years, a case of calcaneo-valgus of left leg of twelve years standing, arising from total paralysis of gastrocnemius, with contraction of tibialis anticus, extensor longus pollicis pedis, extensor longus digitorum pedis.

On the 25th of Sept., 1840, I operated, by excising a full one-half of an inch

of the tendons of the tendo-achillis, and dividing the tibialis anticus, extensor longus pollicis, extensor communis digitorum pedis. Applied plaster to the wounds, and splints and bandages, so as to maintain the extremities of tendo-achillis in apposition, and those of the other parts.

2d day.—All going on well; makes no particular complaint, and free from every symptom of constitutional irritation.

3d.—Still going on well.

4th.—Removed the dressing; wounds in the anterior part of the leg closed; that in the posterior looks well, is nearly closed, and very little pus discharged from it. Dressed, and applied splints and bandages as before.

6th.—All going on well, with the power of flexing and extending the foot; showing the reunion and restored muscular contractility of the tendo-achillis and gastrocnemius muscles, as well as the antagonist tendons on the anterior part of the leg. From this time all went on so well as to require no particular remark; and in six weeks she wore a laced-up boot, walked with comparative ease, and is now comparatively well and strong. As in the other cases, the leg, which was cold and powerless, acquired an increased degree of heat as well as strength. To aid this, and strengthen the limb more rapidly, I recommended friction with stimulating liniment, as in the other cases.

CASE VIII.—Wm. Bowker, Sheffield, æt. 7 years, has had talipes valgo-calcanus from infancy, supposed to have arisen from a paralytic stroke when six months old. Has no power of gastrocnemii, so that the foot can be pressed upwards until it almost reaches the tibia. When walking, the foot is turned very much outwards, and the malleolus internus nearly touches the ground. On the 26th of February, 1841, I operated by excising 3-16ths of an inch of tendo-achillis, and dressed and bandaged in the usual manner for such cases.

2d day.—All going on well.

4th.—Makes no complaint; removed the bandages, &c. and reapplied them as before. There was the smallest possible quantity of pus under the plaster.

6th.—Can now flex and extend the ankle-joint and toes. From this time

continued to progress in the most satisfactory manner, and in eighteen days could walk easily without any apparatus applied to the foot or leg, having completely regained the power of the gastrocnemius and tibialis posticus and flexor longus digitorum pedis.

I could easily multiply cases of a similar nature, but shall only add one more, where I excised about half an inch of the tendons of the biceps flexor cruris, the semimembranosus, the semitendinosus, and the gracilis, in a case of such extreme weakness of these muscles, that the tibia and fibula could be so much flexed upwards on the femur as to form a very considerable angle at the knee. Although both legs were similarly affected, I only operated on one, the left, at first, being much the worst. After the operation, having the wounds closed with plaster, and the legs flexed at right angles with the thigh, splints and bandages were then applied to retain it in that position, so as to allow the divided extremities to reunite with the least possible intervention of new tendinous substance between them. Every thing went on to my entire satisfaction; and in ten days such firm reunion of tendons had taken place as to offer considerable resistance to extending the leg completely. In two days more I did not hesitate to let the patient stand on his legs; when it was most interesting to remark the improvement which had resulted from the operation, this leg being now perfectly straight, the other still falling back in the old form. The day fixed for the operation on the second leg the boy was attacked with scarlatina, which, of course, caused it to be postponed. However, I intend shortly to perform the operation, and have no doubt but the results will be equally satisfactory as those which attended operation on the first leg. I have also operated by incising a portion of tendon of the tibialis anticus, extensor longus pollicis pedis, and of extensor longus digitorum pedis, in cases of paralysis of the muscles on the anterior part of the leg, with similar results.

I believe this operation is entirely new; and I trust the cases now detailed are sufficient to prove that it is most efficient, and a highly important addition to the resources of our art in an interesting and hitherto incurable class of diseases. It of course requires

great care and consideration in the execution of it, to excise a sufficient portion, and no more; but I hesitate not to say that, when properly performed, it will succeed in every case of the sort I have referred to. I do not profess to have been quite so correct as I could have wished in every case of the kind I operated on from the first. Experience is required in every operation, and particularly so in such as this; because, if too little be excised, it will not excite that activity of contractile power in the muscular fibre necessary for the correct and energetic discharge of its functions: whilst, on the other hand, if this is excited to too great a degree, from too much being excised, the result will be the innervation of the other muscles of the limb operated upon. In a future communication I shall explain my views on this subject, illustrated by the detail of cases in which I have been enabled to restore increased heat, sensibility, and power, to paralysed parts, so that patients who have been powerless of limbs for many years have had the use restored to them, as can be certified by professional friends who have seen the patients and operations. This is accomplished by the converse mode to that now detailed, viz. by the division and ultimate elongation of muscles which had been held in a state of permanent contraction, and thus robbed the limb of that diffusion of nervous energy to the other muscles which is required to ensure and maintain their normal functions.—I am, sir,

Your obedient servant,

JAMES BRAID,
M.R.C.S. Edinburgh.

10, Piccadilly, Manchester,
April 5th, 1841.

ON THE FORMATION OF ARTIFICIAL ANUS IN ADULTS,

FOR THE RELIEF OF RETENTION OF THE
FÆCES.

To the Editor of the Medical Gazette.

SIR,

THE subject of the formation of artificial anus in adults, for the relief of retention of the fæces, having received but little attention in this country, I

beg to forward you some remarks upon it, which I shall feel obliged by your inserting in your very valuable journal, if you think them of sufficient practical importance to merit the attention of your readers. They are for the most part taken from a memoir read by M. Amussat at the Académie de Médecine of Paris, in 1839, with a copy of which he favoured me.—I am, sir,

Your obedient servant,

JOHN ERICHSEN.

24, Welbeck Street, March 24, 1841.

Various operations have been projected, by opening the large intestine in some part of its course, for the relief of retention of the feces, consequent upon obstructions of the rectum, or an imperforate state of the anus. Littre*, as early as the year 1710, proposed in these cases to open the sigmoid flexure of the colon from the left iliac region; but it was not until the year 1776 that any operation of the kind was performed, when Pilloro†, a surgeon of Rouen, was the first to make an artificial anus on the adult, for the relief of retention of the feces; this he did, not according to Littre's method, but by opening the caecum from the right iliac region. Fine†, of Geneva, in 1797, opened the transverse colon from the umbilical region, in a case of retention of the feces produced by scirrhus of the upper part of the rectum.

Although these operations serve to fulfil the indication of relieving the retention of the feces, they are all defective in one most important respect: for, as the peritoneum must, in all of them, of necessity be wounded, an intense and frequently fatal peritonitis is the inevitable consequence. It was to avoid this serious complication that Callisen‡, in 1796, proposed opening the colon from behind, in the left lumbar region, where it is not covered by peritoneum. He once attempted this operation on the dead body of a child, but failing in his endeavour to reach the intestine without wounding the peritoneum, he seems to have relinquished all further idea of it; and it has subsequently been rejected by all those writers on surgery who have

treated of this subject. Sabatier* gives the preference to Littre's operation: Duret†, Martin le Jeune‡, Dupuytren§, and Velpeau||, all reject it on the ground of impracticability; and, like Sabatier, prefer that of Littre. But the operation was not understood: the surgical anatomy of the parts implicated was not sufficiently attended to; and it was not known that the distended state of the intestine lessened the difficulties, and facilitated the performance of the operation.

Amussat, at the time that he was attending the celebrated Broussais for that scirrhus affection of the rectum of which he ultimately died, was led to reflect on the resources that surgery offers in similar cases; and after making some experiments on the dead body, with the view of contrasting the merit of the different operations that have been proposed for the formation of artificial anus in cases of obstruction of the large intestines, he became convinced that the operation proposed by Callisen, if somewhat modified, was not only practicable, but safe. He soon had an opportunity of putting this opinion to the test of experiment, and has since performed this operation twice with complete success.

Before describing the operation itself, it may be as well to give a very brief account of the surgical anatomy of the parts concerned, namely, the left lumbar region and the corresponding portion of the colon, more especially as they have hitherto been little studied in relation to surgery. The lumbar region may be said to consist of two distinct parts, namely, the abdominal wall itself, and the colon, with a portion of the peritoneum which fixes it to that wall. As the different structures that enter into the formation of the abdominal wall in this situation are fully described in all works on anatomy, they need no further attention on our part; but it is with the anatomy of the colon, and with its relations to the peritoneum, which are of the greatest importance in reference to the operation proposed by Amussat, that we have to do.

§ Systema Chirurgiæ hodiernæ. Hafniæ, 1800.

After having detached, layer by layer, all the tissues that cover the colon in this region, it will be seen that the peritoneal investment of this intestine is wanting in its posterior third, which, in this respect, resembles the anterior surface of the bladder. This disposition of the serous membrane gives a peculiar character to the colon, and causes it to differ completely from the other intestines; enabling the surgeon to open it without penetrating into the peritoneal sac. Where the serous membrane is wanting, the colon is covered by several layers of dense and strong cellular tissue, which alone separate it from the quadratus lumborum.

Amussat states that out of the great number of bodies that he has examined with this view, he has never seen a mesocolon in the *left lumbar region*; but, on the contrary, the intestine is always closely attached and adherent to the abdominal parietes by dense cellular tissue. In order to judge whether the colon in the left lumbar region be provided with a mesocolon or not, this intestine must be examined from behind, without opening the cavity of the abdomen; for, if it be examined from before, in the usual way, a mesocolon may inadvertently be formed by drawing the intestine forwards, and thus separating the peritoneum from its cellular connections. If the colon be now distended with air or water, care being taken that the fluid does not pass through the ilio-cæcal valve, it will be seen that the extent of this cellular interval will increase in proportion to the distension of the intestine: the peritoneum being pushed back more rapidly and more distinctly than it is even from the anterior surface of the bladder, when that viscus is much distended. In order to judge better of the extent of the cellular interval which exists at the posterior part of the lumbar colon, this intestine should be detached from the body, and then that part of its surface which is not covered by peritoneum may be compared with that which is invested by this membrane. At the same time it may be useful to note the colour of the colon, which differs from that of the small intestines by being of a more greenish tint.

It has already been stated that Calisen was the first who proposed opening the large intestine without wounding the peritoneum. His operation con-

sisted in making a vertical incision from the last false rib to the crista of the ilium, taking as his guide the external border of the quadratus lumborum muscle. He only attempted this operation once, and then failed in his object of not wounding the peritoneum. In consequence of this failure he appears to have been discouraged, and to have given up all further idea of the operation.

The following is a description of the modified operation that Amussat proposes, and which he has already performed twice with success:—A transverse incision is to be made two fingers' breadth above and parallel to the crista ilii of the left side; or rather in the middle of that space which is bounded by the false ribs above, and by the crista ilii below: the incision should commence at the external margin of the erector spinæ, and extend outwards for about four inches. The spinous processes of the lumbar vertebrae, the crista of the ilium, and the last false rib, are the principal guides. The superior margin of the crista ilii is, however, the safest of these, and the transverse incision may be said to correspond to the middle third of this part of the ilium. After having divided the skin and all the more superficial tissues, the deeper layers are next to be incised as they present themselves: if necessary the external border of the quadratus lumborum may also be cut across. The dissection is then very carefully to be carried through the layers of cellular tissue which lie immediately upon the intestine, and the colon sought for: this will in general readily present itself, and may at once be recognized by its colour and distended appearance. The operation may then be completed by passing a tenaculum, or needle armed with a strong waxed thread, into the most projecting part of the intestine, and by this means drawing it to the surface of the wound, in order to prevent it shrinking or sinking back when opened: it is now to be punctured with a large trochar or bistoury; and its contents having been evacuated, the sides of the opening in the intestine are to be fixed to those of the incision in the skin by four or five points of suture, so as to prevent the contents of the bowel being effused into the cellular tissue of the wound. It is of importance to draw the colon well forwards before opening it, in order to prevent its

contents from being effused into the loose cellular tissue of the wound, where they may set up considerable irritation, and retard the union of the parts. If the patient be very fat, the operation will be much facilitated by dividing the deeper-seated tissues in a crucial manner, so as to give the operator more space. When the operation is practised on the dead body, it will be found on dissection that the following are the parts cut through:—After the skin and cellular tissue, the latissimus dorsi will be seen divided towards the posterior third of the incision, and the obliquus externus in the anterior two-thirds of it; the obliquus internus and the transversalis, sometimes the quadratus lumborum, the cellulo-adipose tissue which immediately covers the intestine, and finally the colon itself. Very few vessels or nerves are wounded, as they, for the most part, run parallel to the line of incision; whereas, if the vertical incision of Callisen were adopted, they would necessarily be cut across.

When we compare the different operations that have been proposed for the formation of an artificial anus, it will be found that Callisen's, as modified by Amussat, is the one to which the preference must be given, for *by it alone* the peritoneum is not wounded, and thus the inflammation of that membrane, which is a necessary and so often a fatal consequence of the other operations, is avoided. Besides this advantage, which is of the very greatest importance, Amussat's operation presents several other claims to our notice: as only one side of the colon can be drawn forwards, and not a knuckle of it, as would be the case if the small intestines were operated upon, it is evident that the spur-like process, which has been so accurately described by Dupuytren, must exist to a very small extent; and consequently, if the artificial anus should ever become useless, the natural passage for the feces having been re-established, it could readily be closed up. If, however, the peritoneum should be accidentally wounded in the attempt to reach the colon from behind, even then this operation would be preferable to that of Littre; for the cavity of the abdomen having been opened at its most depending part (in the recumbent position), the fecal matters would have much less tendency to be effused into it, than if it were opened in front.

In respect of not wounding the peritoneum, this operation closely resembles that of puncturing the bladder above the pubes, and below the reflection of the peritoneum. There is, however, one important difference between the two operations, which may influence the result; for in the one case, as the patient lies upon his back, the urine has a tendency to stagnate in the wound, being obliged, in order to escape, to mount against its own gravity; whilst, in the other case, the fecal matters find a ready exit from a wound situated in a depending part.

The question as to the formation of an artificial anus in those cases in which the large intestine is completely obstructed at its inferior part has never been properly discussed, although it is a subject well deserving the attention of surgeons. Most systematic treatises on surgery are silent on this point, and in the journals there are only six cases published in which any operation having for its object the relief of obstructed intestines has been performed on adults. Amussat refers to two preparations in the Musée Dupuytren, which deserve examination as illustrative of this subject. One represents tumors in the form of vegetations arising from the inner surface of the rectum; the other, taken from the celebrated tragic actor, Talma, exhibits a simple and complete stricture of the rectum. These two preparations prove that it would have been possible to have established an artificial anus in these cases, and to have hoped for complete success; more especially in the case of Talma, which was one of simple stricture without any scirrhus disease. Amussat remarks that these cases of simple stricture of the upper part of the rectum, and of the sigmoid flexure of the colon, occasioning death by producing a complete obstruction to the passage of the feces through the intestines, are by no means rare.

With regard to imperforate anus, or rather the absence of more or less of the rectum in infants, Amussat does not think that, in these cases, an artificial anus should be established in the abdominal region, except when the intestine cannot be reached from the anal or coccygeal regions; and then he advises that the colon should be opened from behind in the left lumbar region.

[To be continued.]

ON HIP DISEASE AND LUMBAR ABSCESS.

BY WM. OLIVER CHALK, ESQ.

Resident Surgeon to the Royal Sea-Bathing Infirmary, Margate.

[Concluded from p. 151.]

WHEN the abscess is allowed to form an outlet of itself, I have invariably found that the openings are smaller, fewer in number, more readily healed, and less liable to slough, even should the disease terminate fatally. When the accumulation is large, and the sac has formed in the thigh, some surgeons have recommended the emptying of it, and the compressing of its walls by means of a circular bandage applied tightly around the limb, in order to produce a union, and, with a view of more effectually promoting this process, have used various stimulating injections. This practice, however, is highly objectionable, and generally mischievous to the patient. When the matter finds an exit at the lower part of the thigh, gentle compression by a bandage is of service; but if it be carried too far great irritation ensues; the discharge increases, and fever is excited. The reason of this will be obvious, if we take into consideration the low degree of vitality which characterizes parts affected with strumous disease: in the treatment of scrofulous ulcers the greatest nicety is often requisite in selecting an application that is sufficiently stimulating, without being too much so, and in adjusting the dressings in such a way that over-pressure may not be exerted, and yet adequate support may be afforded to the edges of the wound; for if these precautions be disregarded, the granulations are soon destroyed. Thus, by bringing the parietes of the abscess firmly in contact, we prevent the reparative process, especially if an early opening be effected. Before I became fully aware of this circumstance I had often the mortification of finding my efforts in healing it, under such a plan of treatment, unavailing. There is another objection which applies forcibly to this method—it is, the irritation and suffering produced by the accumulation of pus which necessarily takes place above the bandage all the while the psoas muscle remains affected. At the first opening of the abscess patient

should be confined to their beds for some days, and every care taken to arrest any febrile movement that may arise. If no untoward symptoms ensue after this time has elapsed, they may be allowed to move about on crutches, as, in the earlier stage. The erect position (and consequent dependent state of the limb) is highly favourable to the obliteration of the sac, particularly in the psoas muscle. If patients have been long confined to their bed during the formation and after the opening of the abscess, with the thigh flexed on the pelvis, whenever they quit it the altered position and weight of the limb in the erect posture cause parts once united again to separate, and give rise to considerable suffering and a lingering recovery. Of late years I have had frequent opportunities of comparing the state of individuals who have been confined to their beds during the disease, and those who have been treated on the opposite plan; and I have no hesitation in asserting that the advantages derived from the latter are infinitely greater, both as regards the shorter duration of the complaint and the degree of deformity produced. When we consider the number of years that frequently elapse under the ordinary treatment before the abscess heals, any method that may accelerate the desired effect is invaluable. A period of four or five years very commonly passes over before the healing process is completed. There was an instance last year at the Infirmary, in the case of Wm. Norris, where the discharge from an orifice in the groin had been going on for fourteen years, and continues up to this time.

The sloughing of the orifices of the sinuses in the latter stages of this disorder is of very common occurrence, and it is sometimes followed by hæmorrhage, especially if the case proceeds badly. The walls of the sac become irritable, and discharge profusely; if there has been no pain in the hip and knee since the first stage, it returns with redoubled violence; should counter-irritants have been employed, their evil influence now becomes apparent (by the additional suffering produced in the way already described), hectic fever ensues, and the patient sinks. The treatment of sloughing sores differs in no respect from that already spoken of

in morbus coxæ; the nitric acid lotions, carrot poultices, &c. forming the best local applications. When hæmorrhage occurs in these and other strumous affections, and under very unfavourable circumstances, I have found the Sp. Terebinthinæ the best styptic. In the case of J. S. Beech, æt. 21, admitted May 23d, 1836, and who was discharged Oct. 10, where the abscess after breaking in the groin formed a large tumor in the lumbar region, which was followed by an opening immediately over the sacro-iliac synchondrosis, causing a large sloughing wound, and from which a profuse hæmorrhage proceeded, I succeeded by means of saturating compresses of lint in this spirit, and by applying firm pressure at the same time, in arresting its progress, so that he was enabled to return home, although he died some weeks afterwards. The ulceration that ensues in the latter stage, particularly in cases of long standing, where the vital energies are frequently much impaired, is often very troublesome, and is frequently accompanied by great loss of substance. The local treatment must be conducted with care and attention (in the manner already described when speaking of superficial ulceration in morbus coxæ), and the general symptoms properly attended to. The patient's diet should be carefully regulated at this time. Errors in this respect are exceedingly injurious; and, indeed, throughout the whole course of the disease, I have frequently seen the most promising cases become the most disastrous, in consequence of improper food*.

The case of Edward Brooks, æt. 13, admitted May 16, 1839, and who died Sept. 2d following, is an instance of the kind, and otherwise interesting. The boy was in a state of extreme debility and ill health on his admission; the pulse was small and intermittent, and he suffered from febrile accessions in the evening, followed by perspirations in the morning; the countenance was extremely anxious; the whole surface of the body was of a dark sallow colour, closely resembling jaundice. The ab-

domen generally enlarged; the liver could be distinctly felt extending below the ribs, and was extremely sensitive under examination. His respiration was sometimes impeded, and he had occasional slight cough. The tongue was furred; alvine excretions unhealthy; appetite defective. There was a large accumulation of pus at the upper and inner side of the thigh; he complained of pain in the hip, knee, and thigh, when lying; he walked with difficulty. Immediately over the femoral vessels was the cicatrix of an issue, about the size of half a crown. The hepatic treatment was adopted, and appeared to answer exceedingly well for some time, and his general health underwent great improvement. Meanwhile the sac of the abscess continued to increase in size.

July 11th.—The cicatrix of the issue gave way, and formed a small opening, through which several pints of pus were discharged. (It happened at this time that a sloughing sore had become epidemic at the Infirmary, and almost all persons suffering from ill-conditioned ulcers were attacked with it.) A few days after irritative fever set in, and the cicatrix sloughed. The condition of the patient now became lamentable: the discharge was profuse, accompanied by severe pain, and irritation of the interior of the sac: large sloughs came away through the opening, which by this time exceeded the limits of the cicatrix: the femoral vessels could be seen enclosed in their sheath, and perfectly isolated from the surrounding structures. It seemed that hæmorrhage was unavoidable. Fortunately, however, the sloughing was arrested, the febrile symptoms subdued, and he continued to go on well for several weeks. I was suddenly called to see him one morning: he was suffering from great thirst, together with a distended and painful state of the abdomen. He had vomited during the night. The tongue was furred. The discharge from the abscess, which had previously diminished, was now profuse: the wound, which only a few hours before had been in a healthy condition, was the very reverse: the thigh was exceedingly hot, and painful to the touch. This sudden change, together with the nature of the symptoms, led me to suspect that he must have taken improper food. On inquiry I

* It is a source of extreme regret, particularly to the medical officers of this establishment, that the funds of the charity have been, and continue to be, insufficient to admit of surrounding the building with a wall, for want of which improper food is often admitted, and various other abuses too easily practised.

found that he had eaten voraciously the day before of some that had been procured for him. He died five days after this occurrence.

The appearances after death were as follows:—Chest: The substance of both lungs occupied throughout with miliary tubercles, proceeding to suppuration at their summits; the walls of the left ventricle of the heart hypertrophied. Abdomen: Liver much enlarged and adipous; pancreas unusually firm and granular. The mucous surface of the intestines, from the duodenum to the rectum, presented throughout numerous patches of ulceration, which, in some places, had nearly destroyed the peritoneal covering. The colon was much contracted, and contained some scybulous matter. Local disease: Abscess in the substance of the left psoas muscle, commencing opposite the second lumbar vertebra, which had descended over the brim of the pelvis (producing caries), and formed a large sac in the thigh, extending nearly to the knee: the adjacent muscles were entirely divested of cellular tissue. The sheath of the femoral vessels was entirely laid bare for a considerable distance, but was in a healthy condition.

In my observations on the local and general treatment of these disorders, my aim has been simply to lay down a few leading rules, such as have appeared to me most worthy of attention; for it is scarcely possible to do more than this, when we consider the extent of functional disturbance, and the variety of structure involved in these affections, requiring all our skill and judgment to direct the treatment, which must constantly vary according to the exigencies of the case. For my own part I am very far from believing in the favourite maxim of some members of the profession, "that time does wonders in alleviating scrofulous diseases."

It cannot be denied that there are instances in which patients do recover, under change of air, wholesome diet, &c. with little or no medical treatment; but these form the exception, in my opinion, and not the rule. We have seen that affections of the joint may ensue as a consequence of psoas abscess, but it is by no means impossible that both diseases may arise at one and the same time: yet, as far as my own observation has extended, such cases

are very rare; and indeed I have never met with more than one instance of the kind. This was in the case of John Garrod, *art.* 9, admitted May 18, 1837. The local symptoms were as follows. Circumscribed hardness and fulness of the nates; great pain on percussion over the articulation: the limb shortened, the toe scarcely touching the ground, although there was no contraction of the knee; great pain in the hip and knee at night, and in the recumbent posture. He complained of much uneasiness on pressure in the lumbar region of the same side, and there was considerable fulness, together with tenderness, and a sensation of fluctuation at the lower part of the abdomen.

He stated that about seventeen months prior to his admission, he fell, in consequence of treading on a piece of orange-peel, and struck the hip violently; and that ever since the complaint had been on the increase. Some time previous to this he said that he experienced slight injury to the spine from a sprain; but there was no reason for supposing that this had any effect, as the symptoms commenced simultaneously.

From what has been said of the difficulty of the diagnosis, I will here take an opportunity of giving a brief summary of the symptoms which characterize them.

In *hip disease*, flattening of the nates, uncertain gait, apparent lengthening of the limb from canting of the pelvis; pain confined chiefly to the articulation, ascertainable on percussing the trochanter; rotation, outwards and inwards, flexion and extension, produce pain. In stooping to pick up any thing from the ground the patient bends the knee, but does not flex the thigh on the pelvis: less suffering in the recumbent posture. As the disease advances, lengthening of the limb from the destruction of the ligamentum teres: circumscribed hardness and fulness of the nates; altered situation of the great trochanter; shortening of the limb from dislocation of the head of the femur on the *dorsum ilii*, &c.; suppuration not generally profuse, and not always present.

In *lumbar abscess*, flattening of the nates, uncertain gait, frequent stumbling, canting of the pelvis, and apparent lengthening of the limb; par-

tial flexion of the thigh and knee; rotation outwards, and extension, productive of pain; none caused by flexion and rotation inwards. Pains in the hip and knee, at first erratic, afterwards constant, more especially at night, and in the recumbent posture: thigh flexed on the pelvis when lying. Absence of pain on percussing the trochanter: its prominence from position of the limb greater as the disease advances. Cessation of pain (constituting the second stage) as the matter gravitates and quits the psoas muscle, followed by a soft fluctuating tumor of the nates (the great trochanter retaining its natural position), or on the inner side of the thigh. Frequent exit of matter in the vicinity of the articulation: profuse discharge: shortening of the limb from contraction of the hip and knee-joints.

The following is an account of several post-mortem examinations of cases of lumbar abscess, which had been treated as disease of the hip-joint:—

E. F. Reynolds, æt. 12, admitted May 20th: died August 13, 1837.—Caries of the bodies of the second and third lumbar vertebrae, and brim of the pelvis; abscess in the left psoas muscle; total destruction of the cotyloid cavity, and of the head and neck of the femur: entire destruction of the soft parts; the integuments of the hip and thigh alone constituting the boundary of a vast abscess: there were three openings, two of which had arisen from the sloughing of the cicatrices of two large issues in the vicinity of the joint, and which had caused severe sufferings during life. The liver was enlarged as well as the spleen; the former viscous had contracted strong adhesions to the diaphragm; the pancreas was granulated, and considerably altered from its natural structure and appearance.

E. Hewlett, æt. 9, admitted May 11, 1839, died July following.—Abscess situated in the right psoas muscle; the sac, which was small, commencing opposite the third lumbar vertebrae; the spine free from caries; carious state of the brim of the pelvis; the matter had gravitated along the course of the psoas muscle, producing caries of the cotyloid cavity, and of the head and neck of the femur; the soft parts were entirely destroyed, and the integuments of the hip and thigh formed

the sole boundary of an enormous abscess, the sac of which was filled with pus and dark coagulated blood: there were two orifices, one situated on the upper and outer side of the thigh; another, which had formed over the sacro-iliac synchondrosis a few days prior to death, from which a profuse hæmorrhage took place, and terminated fatally in about thirty-six hours: the cicatrix of a large issue, placed behind the trochanter, was in a state of incipient sloughing on its inner surface.

Chest.—Several small scattered tubercles at the summit of the right lung; a vomica, about the size of a small nut, near its anterior surface; slight but long-standing pleuritic adhesions on the left side; traces of recent inflammation at the lower part of the lung.

Abdomen.—Liver slightly indurated, and somewhat altered in structure, inclining to nutmeg; scybalous accumulations in the colon.

Daniel Macarty, æt. 7, admitted May 18th, died July 20th, 1839.—Abscess commencing in the psoas muscle, opposite the last lumbar vertebra, descending beneath the fascia iliaca, passing over the brim of the pelvis: diseased state of the periosteum and subjacent bone at this point: the cotyloid cavity, together with the head and neck of the femur, were in a state of caries; a small perforation was found at the bottom of the former; an enormous ulcer, situated over the great trochanter, formed by the sloughing of the integuments in the previous situation of a large blister, was the outlet of the abscess.

Chest.—About four ounces of fluid in the pleura of the right side; the pericardial sac contained rather more than an ounce of serum.

Abdomen.—Contained nearly two pints of fluid; liver much enlarged and indurated, presenting a palish mottled appearance on incision, approaching to adipous degeneration; the gall-bladder was distended to nearly three times its natural dimensions, and contained a viscid straw-coloured fluid; the spleen rather small, indurated, and of a brightish red colour; the structure of the pancreas was unusually dense; tuberculated state of the mesenteric glands, with disease of the glandulæ agminatæ; scybalous accumulations in the colon.

Nancy Lockington, æt. 9, admitted

May 9th, and discharged Oct. 23, 1839.

—The patient did not die until the following winter, when I had an opportunity of a post-mortem examination. The abscess was situated in the left psoas muscle, and had descended beneath the iliac fascia, producing caries of the brim of the pelvis, and incipient consecutive disease of the hip-joint. The child died of phthisis. The left lung was completely solidified, from summit to base, by tubercular deposit, and there was an enormous cavity in the centre: there were other appearances of visceral disease, but as I did not take notes of the case at the time, I am unable to enumerate them.

Frederick Rose, æt. 18, admitted May 13th; died the 22nd of the same month. —Small abscess situated in the right psoas muscle, the matter from which had descended beneath the iliac fascia, over the brim of the pelvis (which was slightly carious) to the hip-joint; the cotyloid cavity was entirely destroyed by caries, as well as the head of the femur; there was total destruction of the soft parts, so that the integuments of the hip and thigh were the boundaries of a vast abscess; the head of the femur protruded through an opening which formed the outlet to the abscess during life.

Thoracic viscera healthy.

Abdomen.—Liver enlarged, adipous, and of an uniform dull yellow colour throughout its whole substance; strong adhesions to the diaphragm. Spleen enlarged and solidified; pancreas small, atrophous, flabby, and of a dull reddish hue.

Eleanor Stephens, æt. 12, admitted May 16; died July 19, 1840. Abscess situated in the right psoas muscle, arising from caries of the last lumbar vertebra; the body of the latter being nearly destroyed by it; the matter had descended beneath the fascia iliaca, following the course of the psoas muscle, to the hip, communicating with two orifices, one on the upper and inner side of the thigh; the other near the great trochanter. The capsular ligament of the hip-joint was entire; but on examining the cavity the ligamentum teres presented a purple tinge, and was somewhat thickened. On examining the head of the femur I observed a blackened appearance, which was perceptible through the investing

cartilage. On cutting through it I found the parts in a highly softened state: the cancellous structure of the bone could scarcely be recognised. Chest: slight pleuritic adhesions on both sides. The thorax contained about twelve ounces of serum, and the pericardium three. Miliary tubercles scattered throughout the substance of both lungs. Abdomen: liver enlarged, firmer than natural, highly congested, and here and there of a mottled yellow colour. The gall-bladder distended with bile of a very bright yellow. Spleen unusually hard, containing a small tubercular deposit in its substance.

Remarks on Sea Air, Bathing, &c.

The curative influence exercised by sea air and bathing, on scrofulous diseases, seems, as far as I have been able to observe, generally admitted by the majority of the medical profession: such being the case, it may appear presumptuous on my part to combat an opinion so commonly received; nevertheless I will venture to offer a few remarks on this subject, which are somewhat opposed to it.

It seems to me that a residence at the sea-side acts as variously on the constitutions of scrofulous patients as it does upon those who labour under other chronic diseases. The opportunities for observation are ample: for almost every variety of chronic affection may be witnessed at one time or other at this Infirmary, especially among the out-door patients. Some individuals, on their arrival, experience an exacerbation of their symptoms, loss of appetite, and other derangement of the general health, and an increase of the local disorder: upon others, little or no apparent effect is produced: whilst a certain number derive so much benefit in a short time that it would lead one to imagine that a speedy cure was about to be effected; and in a few instances it cannot be denied that it really happens. If a sea-side residence were so favourable to the cure of scrofulous maladies generally, it would follow, as a matter of course, that those who lived on the sea-coast should be particularly free from its influence; but this is contrary to the fact. The causes of the tuberculous, or phthisical diathesis are as common to it as to other parts of this country: some localities,

indeed, being more favourable to its production than others. Some of the severest cases of strumous disease received at the Infirmary have occurred amongst those who have been bred and born at the sea-side. Phthisis, the most destructive form of scrofulous disease, is common on the sea-coast.*

It may appear, perhaps, from the preceding observations, that I consider sea air, &c. prejudicial to strumous affections generally: this, however, is far from being the case: they are only offered as a caution to those who entertain an idea of their specific influence in curing them. Sir Arthur Clarke, of Dublin, (who had extensive opportunities for observation) in his *Treatise on Bathing states*, that he never saw any good arising from it in these cases. In my opinion, however, sea-bathing, judiciously conducted, and combined with proper care and attention to the general health, is often of the greatest service. If much visceral disturbance exists, I have invariably found cold bathing uncertain, and often injurious in its effects: the warm bath forms a much safer means in such cases; but even this should be carefully used. The object of all bathing is the same, viz. to excite an action on the skin in a greater or less degree; and whenever it fails to produce this effect, some mischief commonly follows. The mode of cold bathing adopted at the Infirmary consists in immersing the patients once or twice only, and not allowing them to remain in any longer than is necessary to accomplish this. The warm bath is usually applied at a heat of 96 or 98 degrees, and persevered in for ten or fifteen minutes. My own plan of late years has been to use it of the latter heat, only allowing the patient to remain in five or six minutes. I have been induced to adopt this method, as I have found it far more beneficial than a longer time. In using the vapour baths it is best not to immerse the head. Few patients can sustain a course of bathing with the whole person exposed to the influence of the vapour, without injury to the general health. The douche baths, warm and cold, form an admirable relief in affec-

tions of the joints, spine, rheumatic affections, &c., and are often productive of great relief.

On the use of the Preparations of Iodine.

In the year 1832, I was requested by Dr. Canham (to whom the Infirmary must ever remain indebted for the introduction of the iodine treatment) to read M. Lugol's treatise on scrofula, and to place some patients under the treatment. From the very little knowledge I then possessed of those preparations I felt very sceptical as to the result, and entered on the plan with some reluctance. It was begun in one ward only; but it very soon became obvious that iodine was a remedy of much efficacy and power. The excellent effect produced on scrofulous ulcers generally was remarkable; sores hitherto unmanageable soon assumed a healthy aspect; glandular tumors were readily absorbed under its influence, or got rid of by suppuration. The peculiar power of remedying ill formed cicatrices, noticed by M. Lugol, could not fail to strike our observation. Chronic abscesses, which had hitherto resisted all the ordinary means, soon healed under its influence.

It would be foreign to my present purpose to offer any more than a few cursory observations on its mode of application at the Infirmary. A mild ointment of iodine, and iodine of potass, is commonly used as a simple dressing to the sores; and the use of sea-water (which formed a very irritating application to the wounds, generally speaking) is for the most part abandoned for the iodine lotions. Iodurated fomentations are much used, and are found highly useful in some forms of the disease, especially in strumous ophthalmia. The ointments of iod. of mercury, sulphur, and lead, have been found very useful, especially in certain forms of skin disease. The internal exhibition of the remedy is now chiefly confined to the iodides of potass, iron, and mercury; the latter is prepared from Lugol's formula, and not from the Pharmacopœia.

In careful hands the various preparations of iodine cannot fail to prove highly beneficial and useful: and their introduction must be considered one of the greatest improvements in modern therapeutics.

* Whenever patients are received at the Infirmary in the latter stage, the symptoms invariably increase.

MEDICAL GAZETTE.

Friday, April 23, 1841.

“Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
 publicum sit, dicendi periculum non recuso.”

CICERO.

THE NEW REGULATIONS OF THE
UNIVERSITY OF CAMBRIDGE.

OUR readers will have observed with some interest that the University of Cambridge has taken part in the present general movement in medical affairs, and has published a new scheme of medical education for those who are desirous of its license to practise. The main object of the scheme, of which we gave a copy a fortnight since, appears to be to increase the length of study, and to add several new subjects to those with which an acquaintance has hitherto been required. Its publication has excited much surprise among those acquainted with the usual proceedings of the University, in consequence of its tacitly admitting some important principles to which the authorities had hitherto been supposed adverse, and of its tending to give the system of Cambridge medical education more of that popular and general character which had hitherto been peculiar to the younger universities.

It is admitted now in words, which has long been matter of fact, that the University does not afford all the education which its examinations require that the candidates for its degrees should have received. Hitherto the standard of the examinations (at least as far as the questions asked gave evidence of it) has been much above that of the instruction afforded in the University itself. For although its Professors of Anatomy, Medicine, Chemistry, and Botany, are second to none in the extent and depth of their several scientific acquirements, and in their

fitness for teaching, yet it has been but too evident that the limited means of practically studying the most important departments of the science—anatomy and clinical medicine—have put it out of their power to give their pupils that knowledge which they felt to be necessary to practitioners. Certificates of having attended hospital practice in other places than Cambridge have therefore been for many years required; and in general it has been supposed (though not expressly required) that anatomy has been studied by dissection in London or elsewhere. In the present scheme, however, foreign study is demanded to a much greater extent. Lectures must now be attended on all the old subjects, and, also, on medical jurisprudence, surgery, midwifery, and practical anatomy,—all of them lectures which neither ever have been, nor are ever at all likely to be, delivered within the precincts of the University.

Now we cannot but greatly doubt the wisdom of a measure such as this. If the University has hitherto had any reputation for the medical education which it has afforded, and which, as far as it went, has always been of the highest order, this scheme must tend to neutralize that reputation, by admitting, even in this limited extent of study, a suspicion of inferiority or insufficiency. By allowing and even encouraging its candidates for the license to obtain all their medical knowledge in the metropolitan schools, the University goes far towards assuming the character of a mere diploma-giving body, and towards entering into a class of institutions by whose association it cannot but be deeply disgraced. It is evident that the tendency of these regulations will be to make all Cambridge medical students attend their lectures in London; for some of those required are not given at all in Cambridge, and for these therefore they must study in

London, or in some large medical school; and of course, as a matter of convenience, the majority will attend their lectures at the same time and place, and will therefore separate themselves as much as possible from the University, with which it would have been for many reasons desirable that their connection should be maintained. It seems to have been forgotten that the defects of the system hitherto have been those of a want not of oral but of clinical and practical instruction, and that against these the present arrangement does not provide much more than the former did: while it adds nothing of importance or value to the practical part of education, to compensate for the discredit which it casts on that which has hitherto been given. We repeat, therefore, that by almost ceasing to offer to educate physicians, and to render its graduates fit for the reception of its diplomas, the University of Cambridge is in danger of falling into the same class with those of Erlangen, Tübingen, and others, that confer degrees on those with whom they have before had no connection whatever. Of course we do not mean that it can ever fall to their level; we cannot imagine circumstances that would so degrade it; but the danger is lest it should fall to the same class with them, and others, in which diplomas, but no adequate instruction, are given.

That such an error as this appears to us should be committed, is the more strange, when it is considered how little it is necessary that Cambridge graduates should be subjected to the course of education now made compulsory upon them. The present curriculum is actually, as far as lectures are concerned, almost identical with that established by the Society of Apothecaries, against which the most reasonable complaint has always been, that it requires the study of a number of

subjects more or less irrelevant to the actual practice of medicine. And against this objection the only rational answer ever made has been, that the study of these subjects has a tendency to elevate the mind, and to increase the intellectual capacity, of the student: to prevent his becoming a mere empirical practitioner, and to give him, as far as possible, the exalted tastes, and the powers, of the man of science. Whether they do so or not may be much questioned; we greatly doubt it; and are, at any rate, sure that the general discipline of the intellect ought to be completed before the study of medicine is commenced; for surely it is absurd that a man should be studying a science, and learning to study, at the same time. However, as we have said, this is the best argument that can be advanced for the introduction of the collateral sciences, into the course of medical studies.

But, for this purpose, these sciences are, or ought to be, altogether unnecessary to Cambridge graduates. The previous studies of the University have for their especial object to render them fit for the study of all other sciences; and in reference to the science of medicine, to teach them, if not to be physicians, at least how they may learn to become so. The intellectual discipline of the graduate is supposed to be perfected when he takes his degree in arts, or has kept the terms necessary for that degree; he might therefore, and ought to, proceed at once to the practical study of the science of his profession. To him chemistry and botany should be only adjuncts to physiology, which, if any one can do it, he ought to be able to contemplate in all its wide extent, as a science involving the applications of the principles of nearly all sciences, whether of dead or living matter. To practical medicine, chemistry and botany, as at present taught, they have no direct re-

lation whatever; unless they are studied as sciences merely, and for the sake of intellectual exercise, for which purpose mathematics and comparative anatomy would answer as well or better, they are absolutely unnecessary even to the ordinary medical student. To the Cambridge graduate we are bound to regard them as superfluous.

Again, with regard to medical jurisprudence. It is plain that this can consist only in the application of the facts and principles of medicine in general to the peculiar circumstances in which they become mixed with questions of law; and in all these a generally well-educated man must be supposed able to make the applications for himself, in each case in which he is called upon to do so. It would be a scandal on the general system of the Cambridge education to suppose that those who have received all its advantages are incapable of doing thus much without special instruction; yet this one is almost compelled to suppose, on the evidence afforded by the recently published curriculum.

On the whole, the scheme seems to us very objectionable. It places the graduate of a distinguished University on almost exactly the same level as the student who has just left a country grammar-school. It seems to suppose the one as little capable of guiding himself in his studies, or of appreciating, by his knowledge of the principles of universal science, the facts of a new branch of it, as the other. If the University authorities deem a knowledge of all the prescribed subjects essential to the character of an accomplished practitioner—and on this we would not dispute—they needed only to have given out that these subjects would be included in the examinations; but they might surely have left the mode of attaining such

knowledge to the judgment which all their previous system of education was intended to cultivate and to perfect. Why should they tie down their candidates to all the annoyances of attending this and that course of lectures, when it might be both easier and better for them to study the subject by actual practice? We should have been less surprised if regulations had been published absolving graduates from all necessity of attending lectures, than we are at that before us: such a scheme, though fraught with danger in the case of the great mass of medical students (whose deficiency is generally an inability to study aright, rather than an inability to learn what is put before them), would, we believe, have been perfectly safe to Cambridge graduates. At any rate, all the instruction by lectures which they can be supposed to need might well have continued to be supplied by their own professors: and charged with this, and with their intellectual powers strengthened by their exercise in the ordinary studies of the University, they might safely be trusted to work their own way in the great field of medical science. To suppose the contrary would be to set oneself against the evidence of all past experience, which has manifestly shown that under their old system the doctors of the English universities have been able at all times to place themselves in the very first ranks of their profession, and against the existing fact of their being at the present day in no wise inferior to any of those whose system of education is in future to be imitated.

Another objection urged against the new scheme is, that it is made retrospective, and will, therefore, fall very inconveniently on many who have been leisurely pursuing their medical education, in the belief that the old system would be continued, at least as far as

their interests were concerned. We are not aware of any good reason why, in this instance, the principle hitherto almost universally acted on in the University, of making all changes entirely prospective, should have been departed from. We can hardly suppose that it was thought necessary to do this in order to avoid an accusation of indifference or bigotted attachment to old things: the steady progress of improvement which has long been going on in many departments of the University, would have secured it against conviction on such an indictment: and surely, if there were no very urgent reason for the present precipitancy, it would have been better both for the convenience of those with whose plans the new scheme will materially interfere, and for the maintenance of the good and long established principle of avoiding retrospective changes, to have shielded all but future students in medicine from the demands of the new and burdensome curriculum.

BIOGRAPHICAL

MEMOIR OF MR. WINKFIELD.

To the Editor of the Medical Gazette.

SIR,

I HAVE ventured to indulge the belief, that a brief memoir of the life and character of a real country surgeon—"a man to all the country dear"—who, for upwards of half a century, ruled without a rival in all medical matters over an extensive district of Hertfordshire, will not be without interest to a large body of your readers. Those among them to whom the name of old Winkfield, of Market Street, is familiar, will, I am sure, be gratified by a few brief notices of his birth, parentage, education, and career. Those who now hear the name for the first time, will grieve to think that so much benevolence is gone out of the world, and that they

can never hope to enjoy the privilege of his warm and hearty friendship.

Your obedient servant,
GEORGE GREGORY, M.D.

51, Weymouth Street,
April 15, 1841.

John Winkfield was born at King's Langley, Hertfordshire, on the 12th March, 1752—a memorable year, when the old style was changed for the new. His parents were respectable people, of small independent property. They had nine children, eight girls and an only son, the subject of this memoir. At the early age of twelve years, John Winkfield was apprenticed to Dr. Kirby, of Luton, with whom he resided for seven years. On the termination of his apprenticeship he proceeded to London, and became a pupil of St. Bartholomew's Hospital. He studied surgery under Mr. Pott, but could not have devoted much time to the instructions of this great master; for, in 1772, we find him, after passing a creditable examination, commencing practice at Market Street, being then only twenty years of age. In that village Winkfield continued to practise for the unprecedented period of sixty-two years, during which time he had successively seven partners. He finally retired from business in 1834, when he had attained the age of 82. Mr. Charles Sweeney, now of Upper Seymour Street, succeeded him.

Winkfield, in the course of his medical career, enjoyed the friendship of many of our first surgeons. Sir Astley Cooper, Mr. Cline, and Mr. Abernethy, knew him intimately, and always spoke of him with affectionate regard. Abernethy makes honourable mention of him in one of his works. For those luminaries of surgery Winkfield entertained feelings of regard approaching to devotion. Often have I heard him repeat with pride the casual remark of Sir Astley Cooper, when Winkfield had expressed his admiration of some masterly effort of Sir Astley's skill, "You are a great operator yourself, Mr Winkfield."

On his skill as an operator Winkfield prided himself not a little; and from all I can learn, he really had earned for himself a good name as a bold, skilful, and successful operator. The most remarkable case in which he

was ever concerned was that of a man through whose abdomen a ramrod passed, which penetrated several inches through the back. The man subsequently recovered, without any serious symptoms arising. He was sent for on one occasion to visit a man whose chest the shaft of a gig had entered, and who survived the injury. He was frequently in the habit of mentioning a case of amputation of the arm, which healed without any vessel requiring to be tied. The probable cause of this peculiarity was the previous long-continued pressure of the tourniquet, while the assistance of the surgeon was sought.

His professional reputation stood so high throughout Bedfordshire and Hertfordshire that he was generally consulted in all difficult surgical cases, and the duty of operating generally fell upon him. As an accoucheur, too, he was in high esteem, and his advice was largely resorted to in difficult labours.

With his professional neighbours Winkfield was always a great favourite. He was a constant attendant at the annual dinner of the Medical Benevolent Society held at Dunmow, of which he was long the oldest member. On these festive occasions he always presided, and ruled supreme over the mysteries of the *cuisine*. His epicurean whims were kindly indulged by the country doctors, in consideration of the infinite amusement which they derived from the simplicity and rusticity of Winkfield's character, and his singularly original mode of expression. By the lower orders of people Winkfield was, through life, greatly beloved. He had a ready joke for those who were merry, and a kind word for those who were in affliction. He early secured the esteem and affection of the most opulent man in his neighbourhood, the Honourable Mr. Cavendish, who for many years expended a noble fortune in Market Street. Winkfield was the caterer and field-marshal of the dinner-table; but he was more:—he was the kind and generous distributor of his patron's bounty.

Winkfield passed the latter years of his life at Barnet, with his daughter Mrs. Morison, enjoying, until within a very recent period, surprisingly good health. In the autumn of 1840, he had risen in high health and spirits, looking fresh and rosy; and, ere the family were

stirring, had set off in his pony-chaise to visit Hendon, the scene

"Where once his careless childhood stray'd:
A stranger yet to pain."

Having a strong, almost irresistible, propensity towards bricks and mortar, he stopped, *en passant*, to see the almshouses then in course of erection by the Leather-cutters' Company. Regardless of the risk, and heedless of the warnings of the workmen, he persevered in exploring the building, till unhappily he slipped through a trap-door, and broke his leg just below the knee. His health had shewn symptoms of decay previously, but this serious accident put the finishing stroke to his career. The fracture, indeed, healed, under the skilful care and unceasing attentions of his kind friend and neighbour, Mr. Green, but the constitution gradually gave way. His appetite, at length, totally failed, and he sank, exhausted, on the 28th December, 1840, and was buried in the family vault at Flamstead church. His remains were attended to the grave by a large concourse of people collected from all parts, anxious to evince their sorrow at the loss of so estimable a man. An impressive funeral sermon, preached on the occasion by his old friend, Mr. Wheeldon, spoke his warm but well-merited eulogium, as a kind neighbour—a faithful friend—a skilful surgeon—and an affectionate parent.

Mr. Winkfield was twice married. His first wife was Miss Eliz. Fleming, by whom he had three children, all of whom died before him. He married, secondly, Mrs. Benger, a widow, by whom he had one daughter, married to Mr. Morison, surgeon, of Barnet, who survives him.

My own acquaintance with Mr. Winkfield was comparatively recent. About ten years ago he first called on me, and soon, by his kindness of heart, and singular simplicity of manner, won my esteem and regard. His last visit to me was on the 20th May, 1840, when his appetite and strength were beginning to fail him. On that occasion he described to me a very curious suffusion of vision under which he had formerly laboured. For many successive nights he perceived his white handkerchief covered, as he supposed, with blood, and was with difficulty

persuaded that his nose had not bled. He told me that he had inquired, in vain, from his professional friends, for some explanation of the phenomenon, and was highly gratified when I directed his attention to an analogous case recorded by Dr. Heberden, in the fourth volume of the Transactions of the Royal College of Physicians. On the same occasion Mr. Winkfield gave me the following details of the ages of some of his own family, proving, I think, very incontestibly, the principle of hereditary longevity. Mr. Winkfield's age, at that time, was 83. His father died aged 75. His mother died aged 97. His eldest sister died aged 88. His next sister died aged 93. Another sister was then living (and perhaps still survives) near Windsor, aged 82.

So long a period of active professional life, in a populous and wealthy neighbourhood, ought to have ended in the acquisition of a competent fortune; but his farming speculations, and that unhappy fondness for building, to which I have before adverted, marred this golden harvest. *Duruit edificat* might have been the motto to Winkfield's crest.

Mr. Winkfield, in early life, was tall, and of so slim and slight a make as to have acquired the soubriquet of *Threadpaper*. His complexion was blooming, with bright blue eyes, and light auburn curls. As years advanced, he became stout and corpulent; and as such I first knew him. The animated countenance, the pleasant playful smile, and cheerful aspect, however, never left him. They spoke at once of the warm heart and truly benevolent disposition within, which, for seventy years, had rendered Winkfield, of Market Street, an honour to his family, to his profession, and to his country.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

DR. WILLIAMS in the Chair.

Cases of Paralysis and Spasm of Voluntary Muscles from Sympathetic Affections and Actions of the Brain and Spinal Cord. By PETER NUGENT KINGSTON, M.D. Physician to the St. George's and St. James's Dispensary.

AFTER some general remarks on the influence of the brain and spinal cord on the

motor nerves, partly through the medium of volition and emotion, partly through centripetal nerves, conveying impressions to the nervous centres, and producing involuntary movements; the author observes that, although the existence of certain secondary affections and morbid actions of the brain and spinal cord is admitted, their general history has, as yet, been little developed. Our ignorance, he observes, till lately, that in those transient affections of the voluntary muscles which seem to be excited by impressions on remote organs, and which have been termed sympathetic, the nervous centres with their centripetal and centrifugal nerves always interwoven as immediate agents, preclude our referring such affections of the motor nerves to their real source. And, in instances of more palpable affections of the brain and spinal cord, the relation between it and any coexisting affection of a remote organ is most frequently so obscure, that it is still difficult to meet with cases in which the dependence of the former upon nervous impressions communicated by the latter can be unequivocally proved.

In order to illustrate this subject the author adduces a series of cases witnessed and conducted by himself. He conceives that they may exhibit the share which the impressions arising from disease, in other organs, may have in the production of cerebral and spinal affections; and the effect which these again may have in suspending the control of volition over voluntary muscles, and even exciting in them voluntary movements. In this view he presumes that the remote morbid impressions have not been alone adequate to the production of the involuntary movements.

The cases are grouped by the author under two heads, according as there was or was not actual disease of the nervous centres.

The first case, under the first of these heads, is one of general paralysis, under mucous irritation from the presence of tænia. The second case is one of general paralysis under the irritation of psoriasis.

In regard to these, and many other very carefully detailed cases, the author expresses his objection to the opinion of those who should contend that the observed phenomena arises from a direct sympathy, without the intervention of the cerebro-spinal centre. And he notices the opinion of this effect expressed by M. Cruveilhier, in 1829, respecting the tonic contractions of a painful abdomen.

After proceeding under his second head through a careful series of cases, in which the predisposition to sympathetic affection may be attributed to an actual lesion of

the brain or spinal cord, the author concludes with expressing his hope that the knowledge obtained from such sources may direct us to a discriminating use of *known* remedies which had previously been employed empirically.

The President said, that the paper having involved that very interesting subject, the doctrine of sympathies, he should be glad to hear from the author what were his general opinions on it. He seemed to have adopted nearly the opinion of Dr. Whytt.

Dr. Kingston said that he was inclined to accord with the opinion now generally prevalent, and adopted, he believed, by all the best living authorities, that no sympathy of remote motor organs is ever exhibited, except in consequence of an impression conveyed to the nervous centres, the brain or spinal cord, and from them transmitted to the organ said to be sympathetically affected. He did not, however, regard the spinal cord as some did, as merely forming a part of a nervous circle, through which an impression is conveyed from a sensitive to a motor nerve, but rather as a central organ, to which impressions of one kind are conveyed by one class of nerves, and from which impressions of a different kind, regulated by some natural laws, are conveyed through another class of nerves.

Mr. Cæsar Hawkins said he should be very glad to receive information on a subject nearly related to that of the paper—he meant the treatment of what is called infantile paralysis, the disease in which children lose more or less completely the voluntary power over one or more limbs, without any loss of sensation, or any evident cerebral or spinal disease. He had found severe cases of this kind singularly incurable; slight ones, he knew, admitted of relief from a variety of means; but in others, where the paralysis was complete, he had found almost every sort of treatment wholly unavailing.

The President said many members present could speak on the subject from more extensive experience than himself, but, as far as his own observation went, he had found small doses of calomel the most efficacious remedy. In four or more cases he had treated, they had proved evidently beneficial.

Dr. Merriman said his own experience was nearly to the same effect as Mr. Hawkins's. Severe cases of the diseases were indeed almost incurable; but of all remedies for them he thought the most beneficial was electricity. In two cases, especially, both severe ones, he had seen excellent results follow its employment.

Mr. Hawkins said he had frequently employed electricity, but without avail. He had, however, observed, that in some forms of paraplegia it had remarkable effect in increasing, at least for a time, the involuntary

motions of the limbs, which so often occurred in association with the loss of voluntary power. He thought this was particularly the case in paraplegia from disease of lumbar vertebrae; and he had recently had a case under his care, in which a lad thus affected was treated with galvanism, as well as many other equally inefficacious means. Every time that he was electrified, the lower limbs were throughout the rest of the day, or at least for several hours afterwards, incessantly affected with involuntary motions, like those of chorea, which only gradually ceased and returned again the next time he was similarly treated. Mr. Hawkins then related a singular case of paraplegia lately under his care, in which electricity and all other means had been unsuccessful. The child who was the subject of it was in the habit of walking on his hands, with his legs (which were almost completely paralytic) turned up over his shoulders; and his arms, thus continually exerted, had gained extraordinary power, so that he preferred using them as legs to adopting any measure for strengthening the lower limbs.

Dr. Addison was inclined to ascribe much more value to the use of electricity in cases of paralysis than Mr. Hawkins. In cases of infantile paralysis he thought that he had been able to make out that when one limb only is affected, the case is likely to do well; but if the similar limb on both sides of the body had lost its power, then the case was seldom remedied. In the former class of cases he thought time did more than any thing else: he had seen a considerable number in which recovery had gradually taken place, without its being possible to ascribe it to any remedy, although the child had perhaps been continually under medical treatment. The cases of paralysis, especially benefited by electricity, were those that affect parts of the body in hysterical and nervous persons, and in those affected with chorea, between which and local paralysis he need not say there was a very close connection. In all these electricity properly and assiduously administered was a most valuable measure. The mode followed at Guy's Hospital was the drawing of sparks along the whole or a part of the vertebral column till a distinct efflorescence or redness was produced. In one case the effects had been most remarkable: it was that of a lad in the hospital, whom there was no reason whatever to suspect of deception, and who he thought he could be certain was not guilty of it. He had had for some time almost complete paralysis of one lower extremity; but after the very first time of being electrified he slipped off the stool, and walked away perfectly recovered, and had had no sign of paralysis since. Dr. Addison also related briefly a case at present in the clinical wards of Guy's

Hospital, in which chorea had supervened on paralysis of the facial nerve in a young girl, with considerable alleviation of the latter.

Dr. Mayo related a case of paraplegia which he believed resulted from disease of the arachnoid membrane of the spinal cord, and which had commenced, as he suspected these cases commonly did, with what appeared to be rheumatic pains of the limbs.

CORONER'S INQUEST.

UNFOUNDED IMPUTATION ON A MEDICAL GENTLEMAN.

To the Editor of the Medical Gazette.

SIR,

I BEG to send you the enclosed account of a coroner's inquest which has been held in this city, considering that its more extensive publication in the *GAZETTE* may be useful to the profession, in showing the injury which may arise to a respectable practitioner from the condemnation of his treatment of a case by a medical man who may happen to be called in after him.

Your obedient servant,

* * * *

Coventry, April 17, 1841.

On Saturday evening, the 3d inst. a Coroner's Jury was impanelled at the White Hart Public-house, Much Park Street, to inquire into the death of Frances Brown, wife of David Brown, a watchmaker, residing in that neighbourhood.

Deceased having died on Thursday, the 1st of April, her husband shortly afterwards went to Mr. C. Holt, the Registrar for St. Michael's District, to obtain a certificate of the registry of her death. One of the necessary inquiries of the Registrar is, as to the cause of death of the person to be registered, and on putting this question to Mr. Brown, he replied, as stated by the Registrar, and witnessed by one or two individuals in his office, "Murdered by Doctor West." Naturally struck with astonishment at such a declaration, the Registrar repeated his question, and received the same reply again, or one conveying the same imputation. Upon this, therefore, he felt bound to acquaint Mr. West of what was said, and accordingly did so; and the latter gentleman, not less astonished than indignant at such a charge, immediately took the necessary steps to have the fullest inquiry and investigation into his conduct in the treatment of deceased, whom he had attended as a patient. It will be seen from what follows that Mr. West attended deceased till within a few days of her death, and that Dr. Arrowsmith being called in, led to the discontinuance of Mr. West's visits.

The first witness sworn and examined was Sarah Webb, a practising midwife, who stated that she was called on by Mr. Brown to attend his wife on the 4th of March. That she did so; and after remaining with her for about an hour, or an hour and a half, the symptoms were such that she advised Mr. West to be sent for. Mr. Brown immediately went to fetch him, and shortly after returned in company with Mr. West; but in the meantime the child was born.—The witness then proceeded to give an account of the means used by Mr. West, stating that, to the best of her judgment, he displayed skill in what he did, and acted as she had observed other experienced surgeons do.

Dr. Arrowsmith being next examined, said, I was called in to attend Mrs. Brown on Tuesday, the 30th of March, about half-past three in the afternoon. This was the only time I visited her, and I was then with her about ten minutes. She appeared in a state of considerable insensibility; but I think was conscious of my presence. She was paralysed on the right side, and could not speak; and I understood from some persons in attendance that she had been in that state some days. Her eyes were closed, but she moved her left hand, which, as I interpreted it, she intended to be expressive of the hopelessness of her state. I inquired if she had had leeches to her head, or if her hair had been taken off; and when I was told that these means had not been used, I remarked it was strange treatment to have omitted these and similar remedies. Some medicines were shown to me, one in a small bottle, which I found to contain ether. Of that small bottle the husband told me she was then taking; and I remarked it was ether. I inquired what further means were being used, and was told that Mr. West had ordered brandy and wine, as he considered her complaint to arise from weakness. I said I thought not, and that they had better not give her those things. Nothing further transpired in the room; but when I left the room, the husband came out with me, and I said to him it was not in my power to render her all that assistance she required; but I recommended him to enter her immediately in the Self-Supporting Dispensary. I then left, and knew nothing of what further transpired. I was told by some persons whom I saw in the room that deceased had been delivered about a month before.

Mr. Nankivell, surgeon, examined.—I saw deceased the first time on Tuesday, the 30th of March, about eight o'clock at night. She was then in a state of complete paralysis; she had lost the sensibility of both sides, as was shewn by her not appearing to feel in the least on her skin being pinched; there was also loss of motion on both sides, the

limbs remaining in exactly the same position in which they were placed by a second person. She was in a state of stupor, inclined to dose and sleep, but still capable of being roused to a slight degree of consciousness, as appeared by her fixing her eyes on persons in the room, and by her attempting to put out her tongue when I requested her to do so; but she seemed unable to speak. The urine escaped involuntarily; she was in a profuse perspiration, and her pulse was extremely quick and weak. I heard she had been confined about a month previously; and that a few days before I saw her she had been taken speechless, and lost the use of her right side.

On Sunday afternoon last, about three o'clock, a *post-mortem* examination took place, at which I was present. On opening the head, there was a slight congestion of the vessels of two of the membranes of the brain, the *dura mater* and the *pia mater*. The brain was much firmer than usual at such a period after death. The convolutions of the brain were slightly flattened; the substance of the brain did not contain more than the usual quantity of blood; the choroid plexus was very pale: the principal diseased appearance in the brain was an effusion of serum or watery fluid in the ventricles, and at the base of the brain. The rest of the body was remarkably deficient of blood. There was much less than the usual quantity in the posterior portion of the lungs; the heart was soft and flabby, and contained little blood; the liver, stomach, intestines, and kidneys, were remarkably pale, from containing less than the usual quantity of blood; the spleen was less gorged with blood than usual.—After describing farther the state of the body consequent upon the particular situation of deceased prior to death, Mr. N. continued—My opinion is, that the cause of death was the pressure on the brain from the quantity of fluid it contained. This may have arisen from various causes; but from my not having seen the whole progress of the case, it is difficult, perhaps impossible, for me to say what was the exact morbid condition upon which the affection of the head depended; but from the examination of the body, especially from its exsanguine condition or deficiency of the blood throughout the various organs of the body, it is most probable that the state of the brain was the effect of loss of blood, or of reaction from loss of blood. The serum, or watery fluid in the brain, was likely to be, and no doubt was, the cause of paralysis. I consider the state of bloodlessness of the different viscera one which would be attended with debility and exhaustion, and render it improper to use active depleting measures; and that, in all probability, it would require, in some degree, an opposite treatment. I

therefore infer that wine and brandy would not be injudicious.

Mr. John Bury, surgeon, examined.—I attended a *post-mortem* examination of deceased on Sunday last, and have been present during the whole of Mr. Nankivell's examination to-day. I concur with him generally in the statement he has made, but there is one little point I think he omitted; that is, the opacity of the arachnoid membrane of the brain, and which gave to my mind the idea that the brain had been subject to disease for some time; and this idea is confirmed by the history given by those who say she had been subject to head-ache for many years. On the choroid plexus a quantity of lymph was effused. As to the cause of death, I consider she was a feeble person previous to her confinement, and probably with a diseased membrane of the brain before also, most likely from a severe labour and much hæmorrhage. I am not surprised at the fatal termination of her illness in apoplexy or paralysis. I have been present during the examination of Mr. West, and I am not aware that his conduct or treatment of the woman was at all improper, or injudicious.

Mr. William Laxon, surgeon, examined.—I was present at the *post-mortem* examination of deceased, and have been present during the examination of Mr. Nankivell and Mr. Bury, and I concur in what they have stated as to the appearance of the body, and in the points added by the latter surgeon. I consider that deceased came by her death by the visitation of God in a natural way, and not from any injudicious or improper treatment inflicted by any one. I consider that she died of serous apoplexy, to which she had a predisposition in the affection of the brain.

Mr. Nankivell said he entirely concurred as to the point alluded to by Mr. Bury and Mr. Laxon, respecting the predisposition to disease of the brain.

The evidence being completed, the Coroner observed to the Jury, that from what they had heard in the testimony which had been delivered touching the death of Mrs. Brown, they must be aware that her death was perfectly natural under the circumstances of her case, and that there was in reality no more occasion for holding an inquest upon her than for any other individual dying in the ordinary way. The only thing which made an inquest desirable was, the unfavourable report which had got abroad respecting Mr. West, whose conduct was now proved to have been perfectly humane; who had shown the greatest possible promptitude in visiting the patient when called upon, and evinced the utmost anxiety to relieve and restore her by the skilful mode of treatment he had adopted. After further eulogising the conduct of Mr. West by argu-

ments drawn from the evidence on the inquest, the Coroner expressed his readiness to read the whole or any part of it which the Jury might wish again to hear; but all seemed perfectly satisfied. The Coroner then adverted to the strange representation made by the husband of deceased to Mr. Holt, the Registrar, in answer to the inquiry made by him in the discharge of his duty as to the cause of her death.

The Jury immediately returned a verdict that deceased "Died by the visitation of God, of serous apoplexy."

The inquiry lasted nearly six hours.

NORTH OF ENGLAND MEDICAL ASSOCIATION.

A NUMEROUS and highly respectable meeting of this Association took place at Newcastle last week; Dr. Headham in the chair. Numerous speeches were made in favour of medical reform, which we regret that our confined space prevents us from reporting. It was moved by Mr. T. M. Greenhow, seconded by Mr. Gregory, and unanimously carried—

"That, in the opinion of your petitioners, the Bill for the better government of the medical profession, now before Parliament, is based on principles which are calculated to confer important benefits on the community.

"Your petitioners, therefore, humbly beg that those principles may receive the sanction of your Honourable House."

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.

THE annual dinner of this society took place last Saturday, and was numerously attended, H.R.H. the Duke of Cambridge in the chair. We regret that we cannot make room for any report of the proceedings, but this we regret the less, as it is our intention, on an early occasion, to bring the objects of this institution under the more particular notice of our readers.

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London.

By DR. WATSON.

LECTURE XXXII.

Tetanus. Its symptoms and varieties.

Causes. Diagnosis. Pathology. Treatment: opium; blood-letting; the warm bath; the cold bath.

IN those diseases of the nervous system which have hitherto engaged our attention, the function of voluntary motion, when it has been affected at all, has mostly suffered in the way of diminution, or suspension; the power of moving has been impaired, or lost; there has been complete or incomplete *palsy*. Sometimes, indeed, convulsion, or an irregular and involuntary action of the muscles, has also occurred. But, distinct from the paralytic affections, there is a class of *spasmodic* diseases, of which it is the main and leading feature, that the function of voluntary motion is (not morbidly heightened, as in the preternatural strength of a madman; nor lowered, as in *palsy*; but) *perverted*: performed in an irregular and unnatural manner.

There are two sorts of spasm. One of these is marked by a long-continued contraction of the affected muscles, not rapidly alternating with relaxation: the relaxation taking place slowly, after some time; and then, perhaps, the contraction, after another interval, coming on again. This is called *tonic* spasm; and, by Cullen, spastic rigidity. A very familiar example of it is the common cramp of the leg. In the other form of spasm, the contraction of the affected muscles takes place repeatedly, forcibly, and in quick succession; and their relaxation is as sudden and frequent. This has been named

clonic spasm. We find illustrations of it in convulsions.

Sometimes the two are mixed together in the same disease; certain muscles undergoing convulsions or clonic spasm, and certain other muscles being affected with rigidity or tonic spasm. But it is convenient to keep the distinction in mind.

We recognise these disorders by the unnatural conditions of the *muscles*; but you will please to remember that the fault lies in the *nervous* system.

With regard to spasmodic diseases generally, I may say that some of them constitute the most appalling and fatal maladies to which the human body is liable; and some of them, though frightful to look upon, and productive of extreme distress to patients and their friends, are trivial in their consequences, and scarcely ever attended with any peril to life.

I propose first of all to consider one of the most formidable and worst of these spasmodic diseases, viz. *tetanus*; of which tonic spasm is essentially characteristic. Its name is derived from *τετῶ*, to stretch.

In respect to all those diseases concerning the exact pathology of which we are ignorant, and which we identify by the group of symptoms they present, rather than by any organic changes of structure in any part of the body, the most convenient mode of proceeding will be, first to describe the distinctive symptoms.

Tetanus, then, is characterized by an involuntary, long-continued, violent, and painful contraction—in one word, by *cramp*—of the voluntary muscles of various parts, or of nearly the whole body.

There is no difficulty in recognizing the disease when it is fully formed. But it is of much importance to be aware of the marks of its approach, and of its earliest symptoms; in respect of the treatment to be then adopted.

In general, the muscles that seem to be the earliest affected are those of the neck,

jaws, and throat. The patient feels a difficulty and uneasiness in bending or turning his head; and supposes that he has got what is called a stiff neck. He finds also that he is unable to open his mouth with the customary facility. At length the jaws close; sometimes gradually, but with great firmness; sometimes (it is said) suddenly, and with a snap. In four cases, perhaps, out of five, the disease begins in this way, with *trismus*, or *locked jaw*; so that this last is the vulgar name for the complaint. Along with this symptom, or very soon after it, the muscles concerned in swallowing become affected; and in a short time there comes on what is often the most distressing part of the disorder, an acute pain at the lower part of the sternum, piercing through to the back. This depends, it can scarcely be doubted, upon cramp of the diaphragm. The pain is subject to aggravation in paroxysms; and each paroxysm of pain is attended with increased contraction of the other parts also that are implicated. The spasm extends to the muscles of the *trunk*: to the *large* muscles of the *extremities*; the muscles of the *face*; and last of all, in general, to the muscles of the tongue, and of the hands and fingers, which often remain moveable at the will of the patient, after all the other voluntary muscles of the body have become fixed; and frequently the muscles of the wrists and hands escape altogether.

With respect to *all* the muscles involved, from the time when they are first affected to the time when the disease is relieved, or the patient dies, they *continue* in a state of contraction, and are swelled and hard in their centres. The jaw, for instance, can never be completely opened; and the muscles of the abdomen are so rigid as to make it as hard as a board. But, besides this, they are all subject to aggravations or exacerbations of the spasm, which occur perhaps every ten minutes, or quarter of an hour, and last for two or three minutes at a time; and then the muscles fall back into the minor degree of contraction in which they were prior to the exacerbation. In a very few instances only has a perfect remission of the spasm been observed. The exacerbations usually begin by an increase of the pain felt at the sternum. Sometimes there is no obvious exciting cause of their occurrence; but frequently it is evident that they are brought on by exertions of the body; even by slight movements, such as belong to a change of posture, to the attempt at swallowing, or speaking. As the disease advances, these paroxysms of aggravation become more frequent, and a rapid increase in the frequency of their recurrence is one of the most unequivocal signs that the case is severe and dangerous. The more speedily the intervals between the paroxysms shorten, the worse.

It is a curious thing, that the spasm is observed to give way, sometimes at least, and the muscles to be relaxed, during sleep. To be sure, in the severer cases, the patient is seldom able to sleep; and it may be that in the less violent instances, the spasm abates or ceases, and the exhausted sufferer sinks into repose, in consequence of this abatement. However, a similar phenomenon occurs in at least another of these spasmodic diseases, as we shall see hereafter. Mr. Mayo had a boy afflicted with tetanus, in the Middlesex Hospital. On visiting him one day, he found him asleep, and remarked that he lay perfectly relaxed. The abdominal muscles were soft and yielding, and had not the least tension. The boy was awakened, and at the instant the full tension of the muscles returned: not being farther disturbed, he fell asleep again in a few minutes, when the muscles again slackened; and again, upon his being a second time roused, resumed the state of spasm.

In most cases the strong muscles of the back are the *most* affected, and they overcome those on the anterior part of the body; so that sometimes the patient during the paroxysm rests only upon his head and his heels, while his body is raised into the shape of an arch. This form of the complaint is called *opisthotonos*, a bending backwards. The sterno-cleido-mastoid muscles of the neck have been so stretched and misplaced as to become powerful *extensors* of the head. In a few instances the body is bent forwards, so that the head and knees are in contact, and the patient is rolled together like a ball. This is called *emprosthotonos*. In the only example of *emprosthotonos* which I ever saw, these two conditions alternated with one another. The patient was a girl, in Edinburgh, under the care of a friend of mine, who took me to see her. It was rather a case of hysteria than of tetanus; but all at once she would be drawn into a position such, that the top of her head, and her feet, were alone supported on the bed, while her body was bent like a bow; then, after a time, with equal suddenness, the opposite posture was assumed, her forehead and knees being brought together. Still more rarely the body is bent to one side. This is *pleurosthotonos*, or *tetanus lateralis*; and this I never saw. Sometimes again, in the height of the spasm, the antagonist muscles counteract each other exactly; and the head and trunk are rigidly extended: and the term *tetanus* is by some writers confined to this form of the disease. It is called *trismus* when the jaw only is affected.

It is well to know that these varieties occur, and may be looked for; but in all of them—trismus, opisthotonos, emprosthotonos, or pleurosthotonos—it is the same disease: and the prognosis is not altered,

any more than the diagnosis, by the variety that happens.

During the fit of exacerbation, the aspect of the sufferer is often frightful. The forehead is corrugated and the brow knit, the orbicularis muscle of the eye rigid, the eyeball motionless and staring, the nostril spread, the corners of the mouth are drawn back, the set teeth exposed, and all the features fixed in a ghastly grin—the true *risus sardonius*. The tongue is apt to get between the teeth, and to be severely bitten.

All the contractions are attended with intense pain. You may form some notion of the severity of this pain, if you have ever been troubled by spasm of the gastrocnemius, or cramp of the leg, and if you can bring your mind to conceive that the same sensation which you then felt in the calf, involves nearly all the voluntary muscles of the body. The pain is worst during the exacerbations, and that which is experienced at the sternum is commonly the most complained of. Even to this, however, there are occasional, though very rare, exceptions. Sir Gilbert Blane has described a case of tetanus, which ran the usual course, and terminated fatally, yet the patient suffered no pain: the sensation excited by the violent muscular contractions was a sort of tingling, of rather a pleasurable kind.

So violent are the contractions sometimes, that the teeth have been broken by them. There is one case related in which the thigh-bones were fractured by the forcible action of the femoral muscles; and another in which the psoas muscles were found, after death, to have been torn across. Dr. Latham tells me that he once saw one of the recti muscles, in front of the abdomen, thus rent asunder.

With all this disturbance of the muscular system, there is commonly very little derangement of the other functions of the body. The disorder is almost always attended with obstinate costiveness; partly, perhaps, from the spasmodic closure of the anus, partly, perhaps, in some cases, from the medicines that are given. When stools are obtained they are usually very offensive and unnatural. There is no fever. The pulse and respiration are quickened, and a sweat frequently breaks out, during the exacerbations, from the pain and anxiety then experienced; but this is not the case during the intervals between the paroxysms. In the last stages of the fatal cases, the pulse becomes quick and feeble, and the sweat is cold, as in other instances of approaching dissolution.

What is still more worthy of observation is that the mental functions are unaffected. There is seldom any delirium, or coma, or disturbance of the intellect. These symptoms only appear (if they appear at all) when other indications of the failure of the powers of life come on.

The mode of death, in this disease, seems to be of a mixed nature. Partly it appears to result from apnoea: the thorax being held as in a vice by the spasm of its muscles, and the breathing for a time suspended, or much embarrassed: partly, and chiefly, it occurs from asthenia: the power of the heart flags and is exhausted by the continuance of the suffering, by the fatigue and expenditure consequent upon the muscular action, and by the patient's inability, in many cases, to take sufficient nourishment. When death occurs suddenly, as it sometimes does, in a paroxysm, it is owing, in all probability, to spasm of the respiratory muscles, and perhaps of those of the glottis among the rest.

Most cases of tetanus may be traced to one of two causes: which are, *exposure to cold*, especially to sudden alternations of temperature, and *bodily injuries*. In many instances both these causes cooperate in producing the disease. When it supervenes upon some bodily hurt, it is called *traumatic tetanus*; when it arises spontaneously, or after exposure to cold, it is held to be *idiopathic*. In this country, and I believe in every other, the traumatic variety of the disease is much more common than the spontaneous. But in what manner soever it may originate, tetanus is far more frequent in hot than in temperate climates and seasons. In this case, however, as in so many others, the heat appears to act as a *predisposing* cause only; the exciting cause, in addition to the wound in the traumatic species, being the application of cold (and particularly, according to Hennen, of *cold air in motion*) after the heat, or during the prevalence of hot weather. Thus it is stated that after the battle of Mankau, in the midst of great heats, very few of the French troops were affected with tetanus: whereas those who were wounded in the battle of Dresden, when the weather was cold and wet, just after a very hot season, were decimated by that complaint; which did not spare even those who underwent immediate amputation.

Idiopathic tetanus is extremely rare in this country. Dr. Gregory, of Edinburgh, used to mention in his lectures the case, seen and treated by himself, of a man who, having fallen asleep in moist grass, awoke with a stiff neck, which afterwards went on into regular tetanus. A good example of well-marked tetanus, arising from exposure to cold, is narrated, in the *Edinburgh Medical and Surgical Journal*, by Dr. Hall, of Berwick.

The history of that species of tetanus which occurs in connexion with wounds and injuries presents nothing constant or uniform. The disease is liable to follow hurts of any parts of the body, and of every kind, degree, and extent; from a slight cut or scratch, to a compound fracture, or a severe

surgical operation. It comes on also in various stages and conditions of the injury. Sir James M'Grigor tells us (in the sixth volume of the *Medico-Chirurgical Transactions*) that in the Peninsular war the complaint supervened "in every description, and in every stage of wounds, from the slightest to the most formidable; the healthy and the sloughing; the incised and the lacerated; the most simple and the most complicated." Sometimes, however, the discharge from the wound has been observed to have been remarkably diminished, or suppressed, at the coming on of the tetanic symptoms: and sometimes the wound has healed completely before the commencement of the attack of tetanus. To show you how very trivial the injury may be, how various in kind and in place, I may mention a few instances that have been collected, in illustration of the manner in which this terrible disorder may originate. It has been known to arise from the sticking of a fish-bone in the fauces; from a slight wound of the ear by a musket-shot; from the mere stroke of a whip-lash under the eye, although the skin was not broken; from cutting a corn; from a bite on the finger by a tame sparrow; from the blow of a stick on the neck and on the hand; from a seton in the chest; from the extraction of a tooth; from the injection of a hydrocele; from the operation of cupping.

Nevertheless there are some sorts of injury, and some parts of the body, more frequently than others concerned in the pathogeny of tetanus. The disorder more often supervenes upon injuries of the extremities, than of the trunk, head, or neck; and upon wounds made by puncture, than upon most other hurts. Penetrating wounds in the sole of the foot, such as are not seldom inflicted by treading upon an nail, or a splinter; and laceration, or other violence done to the muscles that constitute the ball of the thumb, are very apt to be followed by tetanic spasm. Some have supposed that the disease has some special connexion with injuries of tendinous parts; but there can be no doubt that it is essentially a malady of the nervous tissue.

The tetanic symptoms occur at no fixed period after the reception of the injury. Professor Robinson, of Edinburgh, was once at table when a negro servant lacerated his thumb by the fracture of a china dish. He was seized with convulsions almost instantly, and died, with tetanic symptoms, in a quarter of an hour. Such a rapid progress as this is, however, quite out of the usual course of the disease: probably fright had something to do with it. Hennen, in his work on *Military Surgery*, states that terror is frequently the immediate antecedent of the attack. In general the tetanus supervenes between the fourth and the fourteenth day

after the infliction of the injury: some time in the second week is the most common period of all. In the Peninsular war it did not commence later than the twenty-second day. In some rare instances its accession is still longer deferred. "Of the nature of the changes that take place in the interval (justly remarks Dr. Alison) we have no information whatever." The longer, however, that the disease delays its assault, in these traumatic cases, after the reception of the local injury, the milder in general does it prove, and the more room is there for hoping that it will end favourably.

When the disorder arises from exposure to cold and damp, it comes on much earlier; often in a few hours. If, for example, the exposure takes place during the night, the complaint may begin to declare itself the next morning.

Although tetanus may be excited by a wound, independantly of any exposure to cold, or by cold without any injury, there is good reason for thinking that, in many instances, one of these causes alone would fail to produce it, while both together call it into action.

After the disease has set in, its rate of progress is various. Almost all writers divide it into acute, and chronic tetanus. But the difference is merely in the degree of severity. When the spasms come on suddenly, recur often from the beginning, and increase in frequency and violence, the chance of recovery is but small. The patient, in these cases, sometimes dies on the second, and generally before the fifth day. If he lives to the ninth day of the disease, his prospect is somewhat better, and the spasmodic symptoms may gradually abate and disappear. Some, however, have died as late as the sixteenth, the twentieth, and even the thirty-fifth day: but this last is very rare.

The idiopathic tetanus, or that which is produced by cold, although it commences earlier, is more generally of a chronic character than the traumatic: that is to say, the spasmodic contractions take place more slowly, and the paroxysms do not increase in violence, and in rapidity of recurrence, as they are apt to do in the symptomatic variety: and accordingly this form of the malady is much oftener, I dare not say cured, but recovered from, than the other.

Diagnosis.—With respect to the diagnosis of tetanus, there is only one point in which it is at all ambiguous or important. There is no other disease that is likely to be confounded with it, except perhaps that extraordinary disease hysteria, which sometimes mimics its phenomena. I have already alluded to one example of this kind that I myself saw. But there is a form of *poisoning* that may easily be mistaken for tetanus.

The symptoms produced by a poisonous dose of strychnia, or its salts, or the vegetables from which it is procured, are the symptoms of tetanus. And as this drug is now readily obtained, and its noxious qualities are well known, it is not unlikely to be made an instrument of suicide, or of murder. It is necessary therefore that you should be acquainted with the effects of this poison, which constitutes the active principle of the *nux vomica*, the *fabæ St. Ignatii*, and the *upas tieuté*. Dr. Christison has excellently well described these effects as they are observable in animals; and I have once, by accident, had an opportunity of witnessing them in the human body. I shall not be wandering from our present subject if I enumerate the symptoms to be expected from a large dose of strychnia; especially as I have lately been advising you to make trial of it as a remedy in certain forms of disease. Dr. Christison, who had made experiments with it upon animals, tells us that the creature "becomes agitated, and trembles, and is then seized with stiffness and starting of the limbs. These symptoms increase, until at length it is attacked with a fit of general spasm, in which the head is bent back, and the spine stiffened, the limbs extended and rigid, and the respiration checked by the fixing of the chest. The fit is then succeeded by an interval of calm, during which the senses are quite entire, or unnaturally acute. But another paroxysm soon sets in, and then another and another, till at length a fit takes place more violent than any before it, and the animal perishes suffocated."

Some time ago I had occasion to prescribe the strychnia for two patients in the Middlesex Hospital, both of whom had paraplegia. I directed one grain to be intimately mixed with crumb of bread, so that it might be divided into twelve pills: and one of these pills, or one-twelfth of a grain of strychnia, was to be taken by each patient every six hours. Unluckily, through mistake or negligence in the person who was at that time the dispenser, a grain of the poison was administered at once to each patient. It was given about seven in the evening. At half-past seven it began to produce its characteristic effect upon one of the patients. He was suddenly seized with tetanic spasms; his legs were separated widely from each other, and rigidly extended: and his head and trunk bent backwards. He was, in fact, in a state of opisthotonos. His abdomen was quite hard, and his limbs stiff, even when the violence of the paroxysms abated. He cried out with the pain at the coming on of these spasms. Any attempt at movement, even the touching him by another person, brought them on. This is just what happens in the disease. The opening of a door, a sudden current of air, the smallest bodily

effort, the act of swallowing, nay, even the imagination of these influences, will be sufficient to renew the spasmodic tightening of the affected muscles. My patient spoke of a particular sense of constriction all over the abdomen, as if it were drawn in. His intellect was quite unaffected. He had two extremely violent attacks of the kind I have been describing, in which he thought he should have died: and to say the truth I was myself horribly afraid of the same catastrophe. Afterwards, from half-past eight o'clock to between eleven and twelve, he had several slighter and shorter fits. He was left weak and exhausted by them: but he soon recovered. I may as well tell you that his paraplegia was not a whit benefitted by this violent action of the remedy.

You may suppose that when I found one of my patients in this alarming state, I became very anxious to ascertain the condition of the other, who had taken the same quantity of the strychnia, and lay in another ward. He told me that he had been for a short period very dizzy, and had trembled all over; and at the time when I saw him, he had a weight or uneasy sensation at the nape of his neck, which drew his head backwards; and he experienced some difficulty in opening his mouth, and in articulating his words. But he thought these symptoms were diminishing rather than increasing. He was perspiring profusely. It is stated by Dr. Christison that if the spasms do not come on within two hours after the poison was swallowed, the patient is safe. It was more than two hours since this patient had taken the strychnia. I gave him a full dose of purgative medicine, which acted as an emetic: and, after he had vomited, the unpleasant sensations about his head and neck left him.

I scarcely knew what to do with the other patient, in whom the spasms had commenced. There is nothing satisfactorily made out, that I know of, concerning the mode of treating such cases. Of course, if one saw the patient early, and knew what he had swallowed, the first thing to be done would be to procure its evacuation from the stomach. But here it had had full time to get into the circulation: and no emetic could have withdrawn that part of it, at least, which had already found its way into the blood-vessels. When I reached him, though the spasms were strong, they were less violent than they had been, and their violence seemed upon the wane: but they were brought on by any almost the slightest muscular effort, or change of position. I hoped therefore that the most dangerous period was passing off, (and so it turned out) and I was fearful of doing harm by exciting those movements of the body which accompany the act of vomiting. I recollected too that another patient in the hospital, under the care of one of my

colleagues, had once been attacked with episthotonos after taking half a grain of strychnia; and that brandy and water had been given to him; and that he got well from that time, without having another paroxysm. So I gave my patient some brandy and water; and he seemed the better for it: but whether or no it contributed much to his recovery I cannot be sure.

Now how are we to tell, when we meet with such symptoms as these, whether they are the result of disease, or of poisoning? The symptoms are the symptoms of tetanus; I know of no means of distinguishing them from the symptoms of tetanus caused by exposure to cold, or supervening upon a wound. Dr. Christison has suggested that the cases of fatal poisoning by strychnia that are quickly fatal, are fatal in a shorter time than the disease ever is. But if the case related by Professor Robinson, in which the negro was dead in fifteen minutes, is to be regarded as a genuine instance of tetanus, this distinction, drawn from the rapidity with which the poison kills, will scarcely hold. Again, persons who have taken an overdose of strychnia sometimes survive the tetanic symptoms, but die afterwards from the irritant effects of the poison upon the mucous membrane of the alimentary canal. This we do not observe in the disease. In suspicious or questionable cases, we must look into the history of the patient; enquire whether he were likely to wish to destroy himself; what he last swallowed, and when it was taken; whether he has lately been exposed to the injurious influence of cold, especially to a stream of cold air while he was perspiring; and whether he has recently received any bodily hurt. By a careful investigation of all the circumstances, we shall generally be enabled to decide the true nature of the case; but it is clearly necessary that our eyes should be open to the possibility of a case of poisoning by some of the preparations of strychnia being palmed upon us as a case of natural disease.

The *pathology* of tetanus is undoubtedly obscure: but not more so, I conceive, than that of those nervous diseases in general which produce violent symptoms, and even death itself, without leaving any traces of their operation inscribed upon the dead materials of the body. Nay, it is not so obscure as several others. I think we may fairly come to the conclusion that the symptoms result from irritation of the *spinal cord*, or of its afferent nerves; and that the *brain* is not involved in the disease. The French (at least some of the most modern writers on tetanus) hold that it is always an inflammatory complaint; and that it consists essentially in inflammation of the spinal marrow: and some of them have sought to remedy it by enormous blood-lettings; from

fourteen to fifteen pounds of blood being taken in the course of a few days by one practitioner; and another bleeding his patient eight times, and applying 792 leeches along the course of the spine, and to the epigastrium. But this doctrine of inflammation being at the bottom of every case of tetanus is contradicted by the plainest facts; and the practice founded upon it has been pushed to a most extravagant and absurd extent. Numberless instances occur of inflammation of the spinal cord and its membranes without any tetanus; and equally numerous examples of tetanus have been met with, when no unnatural appearance at all could be discovered within the vertebral canal. I say we must content ourselves with referring the phenomena of the disease to *irritation*, direct or indirect, of the spinal cord; or its nervous appendages: and I am quite proof against all sneers against the alleged vagueness of that term.

If you *irritate*, mechanically, by means of a pair of forceps, the exposed spinal cord of a recently decapitated animal, a turtle for example, you produce spasmodic contraction of the limbs: what difficulty is there in supposing that some mechanical irritation existing within the spinal canal of a living man may have a similar effect? It may be, and probably is, sometimes, the mechanical irritation caused by the altered state of the blood-vessels under inflammation; for we sometimes find traces of such inflammation in the spinal marrow after death by tetanus.

Again, if you irritate, by pinching, one of the spinal nerves of a turtle whose head has just been cut off—if you irritate one of these nerves in any part of its course, what happens? why the muscles of the limbs contract spasmodically; those on the side to which that nerve belongs, and those on the other side also. That property of the cord comes into play which I have so often mentioned: a property which it possesses independently of the brain; which it evinces when all communication with the brain is cut off; a property, therefore, which may be manifested without any exercise of volition, and even in spite of efforts made by the will to restrain its manifestation: I mean, of course, the property whereby it is capable of receiving impressions through the medium of its afferent nerves, from parts at a distance, and of originating motion in the muscles of the trunk and limbs through the medium of its efferent nerves. By the courtesy of Dr. Marshall Hall I have been afforded the opportunity of witnessing, in the headless turtle, the phenomena that I have been describing to you. Surely they throw a broad light upon the pathology of tetanus, and of some other affections. We infer from them, most legitimately as it seems to me, that the tonic spasm which characterizes the

disease we are considering may be caused by a diseased state of the spinal marrow itself; or by a morbid condition of the nerves that belong to it. In the latter case, irritation is set up at the free extremity, or somewhere in the course, of incident nerves; along these nerves an influence is conducted to the cranio-spinal axis, in which a process or change takes place, whereby an answering influence is reflected to the muscles along motor nerves: and the whole circle of action and reaction is run through with the suddenness and swiftness of lightning, or of thought. You cannot expect that visible marks of the irritating cause should, in all cases, be left upon the body; any more than you could discern the pinch made by the forceps after they were withdrawn.

When, in the experiments to which I have referred, Dr. Hall plucked or compressed one of the denuded spinal nerves, spasmodic motions were excited in the muscles of *both sides*; and *above*, as well as *below*, the junction of that nerve with the cord. This shews that the change (whatever it be) that is wrought in the cord by impressions made upon one of its afferent nerves, is not necessarily confined to the corresponding *segment* of the cord; but may be instantly communicated, in both directions, throughout its entire course: the whole of this centre of the excito-motory system responding to the influence conveyed by a single nerve, as completely as a tight string vibrates from end to end, when struck at any one point. We frequently, indeed, find that the excited motions are more limited: but it is important to mark this ready consent of the whole cord, under sufficient excitement.

Dr. Hall has given certain distinguishing epithets to tetanus, according to the supposed source and locality of the irritation. When the irritating cause operates directly upon the spinal cord itself, he calls the disease *centric* tetanus: when it resides in some part of the body, distant from the spinal cord, he calls the disease *eccentric* tetanus. These are good and intelligible names; and I shall take leave to adopt them.

Observe now how well this explanation meets the facts of the case. We sometimes find the spinal cord or its membranes inflamed, when there has been tetanic spasm. We then refer the spasm to the centric irritation. But in a far greater number of cases we can detect no marks whatever of disease in the spinal canal, but we know that an irritating cause has been applied to parts at a distance: often we have evidence which is visible that a nerve has been injured, torn across perhaps, or half torn, or compressed in some way or other; just as we might compress a nerve, with a pair of forceps, in a decapitated turtle. That experiment shows us that very slight irritation may be enough

to produce the spasmodic action; and we find that slight injuries, as well as severe, will bring on the disease, when, by the operation of certain injurious agencies, the frame has been predisposed, and rendered morbidly susceptible. There is no part of the trunk or limbs which is not supplied with nerves from the spinal cord; and we find that injuries of various parts, or of almost any part, in an individual predisposed to take on the disordered action, will produce it. The exciting cause may be a wound irritating a particular nerve: it may be exposure to cold, acting upon the extremities of various nerves that proceed from the surface: it may be a bundle of worms, irritating the nerves spread upon the mucous tissue of the alimentary canal: for I omitted to state before that some writers, especially MM. Laurent and Lombard, have maintained that tetanus is almost always, even when it supervenes after wounds, the result of the presence of worms in the digestive organs. They have founded this opinion upon the *fact*, that worms have been very frequently indeed found in the stomach or intestines of persons dead of this disorder. I think this is a point well worth attending to. It is objected that worms infest the human body without causing tetanus: but the very same thing may be said of the operation of cold; and of external injuries. Any of these may probably excite the disorder, when the body is preternaturally susceptible of it. The real mystery lies in this predisposition. We have reason to suppose that a high atmospheric temperature continued for some time is *one* predisposing cause; but how it operates, or what is that state of system in which the increased susceptibility consists, these are points concerning which we are really in the dark.

The disease is common enough in the lower animals: and it is frequently *eccentric* in them; brought on by injuries, mostly of the extremities. Locked-jaw is well known in the nosology of farriers. It is not uncommon in the horse after castration. I remember a mare belonging to my father dying of that disease a few days after foaling. Dr. Parry noticed eccentric tetanus in lambs. "I have often seen lambs," says he, "whose ears, for the purpose of marking them, have been bored with a red-hot iron too near the root, so rigid all over with tetanus, alternating with convulsions, that their bodies would project in a right line with their hind legs, when one held them out horizontally by the hind feet." Dr. Mason Good tells us that parrots also are frequently affected with trismus: a calamity which, supposing the bird to be within ear-shot, it would be difficult to commiserate.

We are not advancing any wild theory,

then, respecting the controverted pathology of this disease, when we lay down the following propositions: that it is essentially a disorder of the excito-motory apparatus; that it results from irritation of a peculiar kind, affecting that part of the nervous system; that the irritating cause may be centric, or within the spinal canal itself; and that it may also be, and often is, eccentric, or situated at the extremity or somewhere in the course of one or more of the afferent spinal nerves; and that a certain predisposition of the body is for the most part necessary, to render it susceptible of the disease under the operation of the exciting irritation.

At one time it was supposed that the physical cause of the disease was detected, in the presence of more or fewer thin scales of bony matter, lying in or upon the arachnoid of the cord. I have myself seen these after death preceded by tetanic symptoms. But tetanus often happens and proves fatal without them: and they are often met with when there has been no tetanus. If, therefore, there be any connexion between these thin plates of ossification and the occurrence of tetanus (which may well be questioned) it must be of this kind; that the scales of bony matter predispose the spinal cord, somehow, to be affected by the exciting causes of the disease.

The doctrines recently propounded by Dr. Marshall Hall, of which the importance becomes daily more apparent, and by which his name will be enduringly connected with the physiology of the nervous system, acquire a strong confirmation from the phenomena of tetanus. They furnish a key to many problems which had previously perplexed the pathologist; and they do this simply by distinguishing the proper functions of the two distinct nervous centres; the brain and the spinal cord. But the practical application of these new views is yet in its infancy.

Treatment.—The *treatment* of tetanus is a mortifying subject. The disease is and has always been a lamentably fatal one. Hippocrates says, ἐπι τραυματι σπασμος ἐπιγενομενος, θανασιον, tetanus supervening on a wound, is mortal: and the aphorism holds true, with very few exceptions, in the present day. Almost all the acute and severe traumatic cases are fatal. Hennen declares that he never saw a case of "acute symptomatic tetanus" recover. Dr. Dickson found all curative measures followed by "unqualified disappointment." Mr. Morgan uses these words: "I have never yet seen or heard of an instance of recovery from acute tetanus. Another of Hippocrates's aphorisms is, ὅκοσοι υπο τετανον ἀλίσκονται ἐκ τεσσαρσιν ἡμερησιν ἀπολλύνται; they who are seized with tetanus, die within four days: but he adds ἣν δε ταυτας διαφορῶσιν ἔγχεες

γινούμαι; if they get over this period they recover. And to this we can only add now, that those who survive the first few days, and ultimately get well, recover in a variety of different ways, and under various modes of treatment. But as to the mode of treatment which is to be preferred, or even as to the real efficacy of any mode, there is much room for doubt. Under every plan of management a vast majority die.

Let us briefly pass in review the principal remedies that have been tried, and enquire what degree of success has followed their employment.

One drug from which much benefit has been hoped for, is *opium*. In some spasmodic disorders it is of unquestionable service. Very large doses of it have been given and borne in tetanus; and some have recovered under its use, and more have died.

It is well known that pain fortifies the nervous system against the peculiar influence of narcotic substances. We need not, therefore, be surprised that opium, administered in enormous quantities, in this painful disease, has had but little effect. I was assured by a physician, with whom I formed an acquaintance in Edinburgh some years ago, and who is known, I find, to a student now present, that his own wife, while labouring under a tetanic affection, swallowed, in twenty successive days, upwards of 40,000 drops of laudanum, which is at the rate of more than two ounces a day; in all, more than an imperial quart. The lady recovered. A case is recorded in the 2d volume of the *Medico-Chirurgical Transactions*, in which an ounce of *solid* opium was taken, in divided doses, every day, for 22 days. This appears a more astounding instance than the former; but I am not sure that it was so; for, in this complaint, solid opium does not always dissolve in the stomach. I have heard the late Mr. Abernethy say that he had found enough undissolved pills of opium in the stomach after death, to poison a dozen healthy persons. This fact should teach you, if you resolve on trying opium at all, to exhibit it in a liquid form; laudanum, or a solution of the acetate, or of the muriate of morphia. And it would be well, I think, to combine the external use with the internal administration of opium; to blister the spine, and strew the blistered surface with powdered acetate of morphia, while you give it in solution by the mouth.

It is sometimes a difficult matter to introduce medicine by the mouth, so strong is the spasmodic contraction of the muscles that close the jaws. You cannot get the mouth open. Some persons set to work to heave it open, by levers; and it has been proposed, and I believe practised, to break off or extract a tooth or two, to make a

passage for the introduction of medicine and of nourishment; but I hope you will never be guilty of such clumsy barbarity as this. Food, and physic, may be carried into the fauces or into the stomach by means of a flexible tube: and this may be inserted through the nostril; or through the mouth, by passing it between the jaws, behind the back teeth, where there is always an aperture that will admit a sufficiently large tube.

After all, in respect to the cures that have been ascribed to the opiate treatment, they have all (so far as I know) occurred in cases of the milder or more chronic tetanus; and mostly in the idiopathic form of the disease; and this circumstance makes it a question whether they were *cures* at all: whether they were not simply recoveries.

Dr. William Budd (in the paper already referred to) challenges the propriety, on physiological principles, of giving any opium in this disease. He says "it has been ascertained that the effect of that drug is to excite, and not to quiet, the motor function of the spinal cord: indeed, it is well known that the motor acts of the cord may be rendered much more active and powerful, by giving, before decapitation, opium to animals that are to be subjects of experiment." He considers "these objections, furnished by theory, to be motives sufficient for the future exclusion of opium from the treatment of tetanus."

I had long been aware that the effect of opium upon frogs was to produce tetanic spasms. But in no case of poisoning by opium in the human subject (and I have seen a great many) have I ever witnessed any approach to tetanus: and I much question the safety of arguing, in such matters, from what we know to happen in the inferior animals, to what we suppose would happen in man.

The failure, however, of opium in the severer forms of the malady, and its equivocal utility in any, taken together with these theoretical objections, prevent my recommending opium as a remedy for tetanus.

Blood-letting.—What is the result of experience in regard to blood-letting in tetanus? I am afraid that, as a curative agent, it has very little power over the disease. Yet it may be, and probably is, of considerable use, as an auxiliary to other measures. When the disorder bears any aspect of inflammation—when, for instance, fever is lighted up, and pain is felt along the course of the spine, or when the approach of the spasm is marked by the supervention or the increase of pain in the wound—our chance of doing good by venesection is the greatest. Some of the cases that happened in the Peninsular war, were decidedly benefited by blood-letting practised under such circumstances. I need scarcely say that

though the bleeding, when adopted, should be early, free, and full, so as to produce some sensible impression upon the system, yet we must always use this remedy with caution. The tendency of the disease is to exhaust the power of the heart; and if by one over-bleeding we bring that organ to a stand-still, it may refuse to begin again.

In a complaint which depends so much on irritation, and so often on manifest irritation of external parts, we look naturally to the *warm bath* for help. And it has been fairly tried: and some persons have found it useful; and others have found it useless, doing neither good nor harm; and some have condemned it as actually hurtful.

The *cold bath* has been extolled as a much more powerful agent than the warm; and so, doubtless, it is. But it is more potent for harm as well as for good. For example: a tetanic patient, in St. Thomas's Hospital, was plunged into a cold bath, at his own request. "All the symptoms disappeared (says Mr. Morgan, in a moment; and he was almost immediately taken out of the bath: but he was taken out lifeless." Sir James McGrigor says that, during the campaign in Spain, "the warm bath gave only momentary relief; and the cold bath was worse than useless."

However, the application of cold water to the surface has, in many recorded instances, been of at least temporary benefit and comfort: and, in the West Indies, where the disease is common, the cold affusion still continues, I believe, to be the most favourite expedient. After it, the patient is rubbed dry, put to bed, and has laudanum administered. I have again to observe, of this remedy also, that it is chiefly serviceable in the idiopathic form of tetanus. It has been tried upon animals. Dr. Parry says that it was quite unavailing in the case of certain lambs that had the disease. In a note which I made at the time of Mr. Abernethy's lecture on Tetanus, I find the following statement. "The effect of cold in diminishing excessive muscular action was strikingly shewn in the case of a horse belonging to Professor Coleman, which had tetanus. The animal was slung, and carried out of the stable, and laid on the snow, which was then on the ground: and he was covered over with snow also. A horse affected with tetanus is a curious sight. His legs straddle, and become stiff; his ears are pricked up; and his tail sticks out. In this case, on the application of the snow, his ears sunk, his tail became pliant, and the rigidity of his muscles was removed. He was again taken into the stable, and the spasms returned." Mr. Abernethy said, that were he himself the subject of tetanus, he would desire to have the cold affusion tried. If you are willing to assay the same remedy, do not

plunge your patient into a cold bath, but take him out of his bed on an extended sheet, splash him well with cold water, wipe him dry, and place him in another dry bed. This will often, for a time at least, diminish the spasmodic action; and the patient will sometimes sleep comfortably after it.

ON THE SYPHILITIC DISEASES OF THE LUNG.

BY WILLIAM MUNK, M.D.

Physician to the Tower Hamlets Dispensary.

[Concluded from page 182.]

(For the *Medical Gazette*.)

As secondary symptoms in general may show themselves at very different periods from the primary contamination, so may chronic syphilitic bronchitis originate at short or distant intervals from the original attack. Its order of occurrence, in relation to other secondary phenomena, cannot, I believe, in the present state of our knowledge, be positively indicated; but the observations I have hitherto made tend to show that it is most usually observed late in the series. I have known it take precedence of the affection of the throat; but far more frequently it succeeds to this, the morbid action creeping gradually and slowly along the larynx and trachea into the bronchial tubes. In such cases the attack presents many of the phenomena, and follows much the same course, as common catarrh. There is first the affection of the throat, indicated by change of colour, slight tumefaction, a sense of roughness and pain about the part, with some difficulty of swallowing. The voice may next become somewhat hoarse; there is tickling or irritation in the larynx; frequent, short, dry, teasing cough, and, after a time perhaps, sense of slight heat within the chest, soreness beneath the sternum, and more or less constriction. The character of the cough becomes now either much modified or altogether changed—a circumstance which depends on the persistence or cessation of irritation in the mucous lining of the larynx. Should it continue, the symptoms depending thereon are combined with those to which the bronchial affection gives rise, and are, according to their severity, proportionally modified; the cough, though

still frequent, short, and teasing, is from time to time more or less bronchial in its character, is attended with expectoration, seems to implicate the whole chest, is deeper toned, more sonorous, and preceded by a tolerably full inspiration. Should the laryngeal irritation entirely subside, the first-named characteristics of the cough cease, the last-mentioned becoming predominant and ultimately existing alone. This, however, is but rarely the case; for the erythematous condition of the larynx commonly continues, and, giving rise to short and hacking cough, with occasional attacks of a bronchial nature, together present that resemblance to phthisis from whence has originated the mistaken diagnosis before alluded to.

From the inner membrane of the air-passages, when once affected, a secretion is soon poured forth; from the larynx at first of a tough clear mucus, expelled with difficulty; from the bronchiæ, of a thinner, but, nevertheless, tenacious fluid, abundant in quantity, and, by its presence, obstructing the tubes, giving rise to wheezing and some shortness of breath. Its physical properties eventually alter; it loses, more or less rapidly and completely, the mucous character, becoming abundant, purulent, and diffident. This condition of the expectoration, when the attack is fairly established, has been alluded to by most writers. A brief continuance of this abundant purulent expectoration suffices to produce hectic, even if hectic of a syphilitic character has not already appeared. Commonly, however, some traces of feverish disease will be detected ere the expectoration arrives at this stage. In either case, indeed, it will be found that, upon the supervention of purulent expectoration, symptoms of a hectic type will appear, or, if already present, be materially aggravated.

In the sketch I have now given of the progress of this disease, I have taken, as an example, a well-marked case running a somewhat rapid course. In the majority of instances it will be found that the symptoms depending upon laryngeal or tracheal irritation persist for some considerable time alone, and are only gradually and slowly combined with those of bronchial inflammation.

From my own observation I can say

but little regarding the morbid appearances presented by the bronchial membrane when affected with syphilitic inflammation. I am glad, therefore, upon this point to be enabled to adduce the opinions of a gentleman of great experience, whose attention has for some years been given in an especial manner to the effects of syphilis upon the pulmonary tissues. My friend Dr. P. D. Sadowski, in a communication with which he has favoured me, dated Prague, July 18, 1840, states, in reply to some inquiries, that a very common consequence of syphilitic bronchitis is ulceration of the membrane; that the individual ulcers are small in size, but exceedingly numerous, and may, in some instances, be detected over the greater portion of the membrane, even in the smallest tubes. The following case, which proved fatal in September, 1839, and was under my care for the last six weeks of the patient's life, is confirmatory of the opinion above expressed. A young gentleman, then nineteen years of age, contracted syphilis in Paris during the summer of 1837. He was then commencing a tour which it was intended should extend over a great part of the continent, in company with his parents and two sisters. A natural desire for secrecy, and a somewhat rapid change from place to place, were obstacles to efficient treatment and proper medical superintendence. He took mercury, but did so both irregularly and inefficiently. The primary symptoms subsided, and on reaching Vienna, where he wintered, he underwent a course of sarsaparilla. By this he was much benefitted; but, in the autumn of 1838, being then in the North of Italy, was attacked with sore-throat. To this there supervened hoarseness, ulceration of the soft palate, cough, a copper-coloured eruption on the skin, nodes, nocturnal pains, and heavy perspirations. Matters became gradually worse, and I saw him for the first time in August, 1839, about three months after his return to England. He was then confined to bed, was exceedingly emaciated and debilitated, had frequent and distressing cough, copious purulent expectoration, together with symptoms which left no doubt of the existence of laryngeal disease. The chest was perfectly sonorous; but an abundant coarse mucous rhonchus was evident over the

whole lung. He was ordered quinine and iodide of potassium, with anodynes, at night, but sank perfectly exhausted on the 15th of September. Numerous minute ulcerations existed on the mucous lining of the larynx; there were none in the trachea; but below the bifurcation they again appeared, becoming more and more numerous the smaller the tubes. In the smallest of the bronchiæ examined there appeared one continuous sheet of ulceration, the individual ulcers having, as it seemed, run one into the other. The bronchiæ were filled with purulent matter, and the inferior lobes of the lung were slightly congested.

The action of syphilis on the pulmonary organs is sometimes evidenced in the form of pneumonia. Of this I have now seen two interesting examples, and some of the recorded cases to which I have above alluded would certainly appear to be of this nature. The case of a soldier, "*Ex male curata lue venerea phthisis factus*," detailed in the *Acta Medicorum Berolinensium*, was evidently of this kind. In thorace (writes the reporter) "*dexter pulmonum lobus maximam partem erat consumptus pars residua pure scatobat cujus etiam magna quantitas in cavitate hujus lateris apparebat. Sinister pulmonum lobus pleuræ erat adnatus substantia ejus extima apparebit integra interior autem vesiculosa substantia erat purulenta et hinc inde vomicis pure repletis obsita*."

In the cases of syphilitic pneumonia which have fallen under my observation, both the local and general symptoms have been more severe than in the ordinary run of cases of syphilitic bronchitis. There has been more marked disturbance of respiration, an expression of countenance indicative of considerable distress, with persistent feverishness; among the symptoms of which heat of the surface has been very prominently marked.

The origin and early progress of these cases I have had no opportunity of watching, the disease, in the only two instances I have seen, having

* No mention is made in this case of the existence of tubercles; whilst in the narration next ensuing their presence is particularly referred to. From this circumstance it seems legitimate to conclude that they were not present in the case quoted in the text, and, consequently, that the disease under which the patient laboured was truly pneumonic in character.

existed for some weeks previously to coming under my care. Respiration has in both cases been considerably quickened—a condition which was much increased both by corporeal and mental excitement; there has been frequent cough, scanty and viscid expectoration, pains in the sides and back, worse during the early part of the night, increased by pressure, and having altogether very much of the character of periostitis of the ribs. In one of the cases there were attacks of a spasmodic character, occurring generally during the first sleep, and, in many other respects, imitating asthma. The pulse, in both instances, was small, frequent, and quick; the skin hot, dry, and harsh; and there were partial sweats at night, occurring more particularly about the chest. The physical signs observed were the crepitant rattle, dullness on percussion, absence of respiratory murmur, blowing respiration, and bronchophony. One circumstance has struck me as curious in these attacks, and as well worthy of remark; namely, the length of time during which the crepitant rhonchus may continue, without giving place to solidification and its attendant physical phenomena. I shall proceed now briefly to detail the two cases from which the above description has been drawn.

A man, aged thirty-one, had, when he came under my care (Jan. 1839), been suffering more or less for upwards of three months from cough, difficult expectoration, hurried breathing, much increased by exercise, feeling of tightness and heat within the chest, together with severe pains of the back and sides, worse at night, and much increased by pressure upon the ribs. There was a good deal of feverishness, the pulse being 96, small, and quick; the skin generally hot and dry, but moist upon the chest; the tongue yellowish, white, and furred. A copper-coloured scaly eruption existed on the forehead, and over other parts of the body, and there was a dark redness of the throat, with slight ulceration. The lower part of the chest posteriorly sounded dull upon percussion, and, corresponding to this, there was bronchial respiration and bronchophony. Higher up there existed a well-marked crepitant rhonchus, more extensively diffused over the right than the left side, but equally distinct in both, and giving way gra-

dually to the signs of solidification. This man had a rather severe attack of syphilis twelve months previously; for which he was mercurialized by a surgeon in Liverpool. In August the eruption made its appearance, and, towards the latter end of September, the thoracic symptoms, without, however, his being able to attribute them to any evident external cause. These had precedence for about two months of the affection of the throat. He was cupped between the blade-bones, took two or three saline aperients, and was then ordered blue pill and opium. A good deal of constitutional disturbance was the result, and, although mercury was ordered in different forms and variously combined, its employment was productive of more evil than good, the pulmonary affection being unalleviated; while the bowels were much disordered, and the whole system thrown into an irritable state. Five-grain doses of iodide of potassium, with tincture of hop, in decoction of sarsaparilla, were now given three times a day, and the compound soap-pill at bed-time. Within a fortnight there was an evident improvement; and in about ten weeks from the commencement of this plan he was perfectly recovered: the general symptoms, no less than the physical signs, having entirely subsided.

The next case occurred in a young man, aged twenty-five; and the symptoms under which he laboured were so nearly like those in the former patient, that it is unnecessary to take up the time of the reader by detailing them. The pulmonary symptoms had existed for about six weeks; and the physical signs consisted of a well-marked crepitant rhonchus, heard in the lower lobe of the left side, and in the middle of the chest posteriorly on the right side, the upper and lowermost portions being free. Bronchophony and bronchial respiration were no where detectable. He experienced nearly every night, sometimes after lying down in bed, sometimes after an hour or more's sleep, and from which he was thus aroused, an urgent sense of constriction and tightness across the chest, with difficulty of breathing and a feeling of suffocation. These symptoms, after a short continuance, subsided; and the remainder of the night was passed in quiet and placid sleep. This patient

had suffered from syphilis eight months previously; and the pulmonary symptoms had arisen about the same time, with nodes upon the shin. He took iodide of potassium, an antispasmodic draught at night, and rubbed mercurial ointment along the spine of the tibia. Under this treatment he improved slowly, but gradually; the crepitant rhonchus diminished, and its place was at length supplied by a healthy respiratory murmur.

The anatomical changes effected in the pulmonary tissues, by the long continuance of syphilitic pneumonia, would seem, from the observations of Professor Van der Kolk, to consist in suppuration, and the formation of abscess. "*Etenim non raro*," says he, "*in perscrutando cadavera siphilicorum qui dum vivebant, phthisici videbantur, inveni in pulmonibus præcipue in medio lobo ulcus quoddam sen pus collectum sine ullo tuberculo cingente, ita ut pus quodam cavo contineretur neque membrana cingens aut induratio posset distingui; in ejusmodi pulmonibus nulla pleuræ pulmonalis exsudatio erat ut externe et tactu etiam pulmones sanissimos crederes; nisi saltem ulcus nimium adesset, nunquam in lobo superiori pulmonum quod in phthisi purulenta semper fere accidit, has ulcerationes inveni sed non longe ab initio bronchiarum, ita tamen ut medium pulmonis parenchyma occuparet.*" —P. 130.

It may perhaps be a matter deserving of inquiry, whether the termination of pneumonia in abscess—a subject upon which there has been much and varied discussion—is not, in many cases, to be attributed to syphilitic pneumonia, or to pneumonia occurring from common causes in an individual contaminated with the syphilitic poison. The opinions of Laennec, Broussais, and Andral, respecting the extreme rarity of this termination, and the statement made by so high an authority as the last-mentioned pathologist, of the facility with which all the appearances of abscess are produced by any thing approximating to roughness or carelessness in the examination after death, have tended, in a very considerable degree, to divert attention from the occurrence in question, and to shake belief in the probability of its existence. The observations of Schroeder van der Kolk may,

perhaps, in the opinions of some, seem obnoxious to the criticisms of Laennec and Andral; but those who, like myself, know the untiring industry with which the Utrecht professor devotes himself to pathological anatomy, and the practical acumen which he evinces in the investigation of morbid structures, will receive with the utmost deference all statements emanating from his pen. These, with the more recent observations of Dr. Stokes, will, perhaps, in some degree, tend to remove the scepticism now existing in reference to abscess as a result of pneumonia.

In the communication from Dr. Sadowski, to which I have before referred, I find the following remarks:—"Does lues ever attack the pleura?" I had under my care," says he, "a few years since, a man who was dying from syphilis. He had lost his palate, portions of bone had come away from the nose, and there was venereal necrosis of one tibia. He had for some weeks complained a good deal of his chest; of acute pains at various parts, increased by inspiration, and by pressure between the ribs. He coughed a good deal, but had little or no expectoration. Upon examination after death there was found in the right side of the chest a considerable quantity of sero-purulent fluid. The pleura presented, at different parts, elevations of a circular or oval shape, like blebs, but less prominent, varying in size from half to nearly two inches in diameter. Of these elevations there were nine; they were caused by the effusion of a thick yellowish honey-like fluid beneath the pleura. A similar appearance has been mentioned to me, by a physician upon whose accuracy I can rely, as having been observed by him when conducting the post-mortem examination of a woman who died suddenly, and of whose history nothing satisfactory could be learnt; but who, the autopsy fully proved, was, at the time of her disease, suffering severely from secondary lues."

The circumstances which, in particular cases, determine syphilitic disease towards the respiratory organs, remain yet to be discovered. Baglivi, in treating of this point, says "*pro varietate conditionis, et status personarum lues gallica variis in locis sedem figit, eosque præ aliis vehementius molestat. Musici ob exercitatos cantu pulmones et ob id*

nimum laxatos, lue gallica pulmones perpetuò ludente divexantur*. These observations, which were doubtlessly penned in reference to syphilitic diseases of the larynx, will, *mutatis mutandis*, apply with equal force to the bronchial tubes and pulmonary parenchyma; and, when carrying out the general principle, of which his statement is but an illustration, we affirm that congenital or hereditary liability to pulmonary disorder, previous or existing disease in these organs, will be likely to direct the ravages of secondary lues to the lungs, we keep within the bounds of analogy as regards other morbid poisons, although we exceed the very narrow limits within which actual observation would confine us. A question of high practical importance, well deserving of inquiry, is, whether pulmonary disease, produced by common causes, in an individual labouring under secondary syphilis, is thereby modified;—whether an appreciable character is impressed upon it, altering its course and consequences, and rendering necessary a different line of treatment?

Dr. Graves, addressing his pupils of the Meath Hospital, on the subject of syphilitic pulmonary disease, asks,—“How are you to recognize it? Mainly (he says) by the history of the disease. If the patient's sufferings have commenced at a period of time after primary sores on the genitals, when secondary symptoms usually make their appearance; if some of his complaints are clearly traceable to this source; if, along with debility, night sweats, emaciation, nervous irritability, and broken rest at night, we find cough; and if this group of symptoms have associated themselves with others, evidently syphilitic, such as periostitis, sore throat, and eruption on the skin, then may we with confidence refer all to the same origin, and may look upon the patient as labouring under a syphilitic cachexy affecting the lungs as well as the other parts.” In this quotation we have a pretty full and very graphic sketch of the circumstances directing diagnosis; yet in the enumeration there is omitted one phenomenon which has been present without exception in all the cases I have witnessed. I allude to the general aspect of the patient, which is often so

peculiar as to declare at once the nature of the disease, or at least to show that the pulmonary affection, whatever be its original cause, is combined with, and its outward indices modified by, the general syphilitic contamination. There is a melancholy and shrunk appearance of countenance; dull, dark, muddy complexion; loss of flesh, particularly manifested in the face, and giving rise to a sunk, haggard, emaciated look. The attitude and manner of the patient, even at rest, are indicative of a want of energy and lassitude; and the actual loss of strength, and consequent incapacity for exertion, is greater than can be accounted for by the loss of flesh. Notwithstanding the presence of all these symptoms, in forming the diagnosis much caution and care are necessary: “we must not draw our conclusion until we have repeatedly examined the chest by means of auscultation and percussion; if these fail to detect any tangible signs of tubercles, we may then proceed to act upon our decision with greater confidence, and may advise a sufficient, but cautious, use of mercury.”

This brings us naturally to the treatment most applicable to the cases in question. Particular cases, according to the difference of their symptoms, demand of course corresponding modifications of treatment; but the point to be now discussed is the relative advantages of the three great remedies of secondary syphilis; to wit, mercury, iodide of potassium, and sarsaparilla; for, in the words of Morton, “ad curationem hujus phthriseos perficiendam omnem merè thoracica et pulmonaria medicamenta sine admixtione antivenereorum nequicquam valere frequenti experientia fretus assero.”

The great armamentarium of almost all the authorities above mentioned is mercury. Morton thus strongly expresses himself:—“Nihil melius excogitari possit quam ulcerum pulmonarium sanationem et crasis sanguinis à fermento venereo eversa restitutionem mercuriali aliqua salivatione tentare. By Dr. Sims it was considered as being the “sole refuge” in this disease, “which never failed performing a cure when taken before the lungs had inflamed and suppurated.” Dr. Graves, it has been shown, advocates no less the employment of this medi-

* Opera Omnia Medico practica et anatomica, 4to. Ludg. 1714. p. 97.

cine. "Under its use," says he, "it is most pleasing to observe the speedy improvement in the patient's looks and symptoms: the fever, night sweats, and watchfulness diminish: he begins to get flesh and strength; and, with the symptoms of lues, the cough and pectoral affection disappear." From mercury I, too, have witnessed most rapid and satisfactory recoveries: but, as regards its employment, my experience has been far less extensive than with the iodide of potassium. I am of opinion that the same rules which guide the practitioner in his choice of mercury or iodide of potassium, as the most appropriate medicine whereon to rely in the treatment of secondary diseases in general, will best direct him in his selection for the cure of syphilitic pulmonary disease: and these being now pretty universally known, need not be dilated on in this place. I would, however, here throw out one suggestion, that mercury should be given only "*priusquam vires a longa morbi protractione jam fractæ fuerint*."

Accumulated, and yet accumulating, experience attests the value of iodide of potassium in secondary syphilis: and I think it will in none be found more strikingly beneficial than in the cases under discussion. The encomium passed by Dr. Graves on mercury might, I think, with equal justice be awarded to this medicine. It is free from the injurious effects which occasionally result from mercury, and, although not invariably applicable, is, in my belief, taken altogether, a more valuable remedy.

With mercury, or with iodide of potassium, I have generally combined sarsaparilla. The soothing effect of this medicine upon the nervous system, apart from its specific influence, appears to me less generally admitted than it deserves to be. Recognizing its extreme value, as well in primary as secondary syphilis, when given in combination with other medicines, I almost invariably employ it. To those sceptical regarding its virtues I would say of it, in reference to syphilitic pulmonary disease, as did Dr. William Hunter of a small bleeding in threatened miscarriage, "it can do no harm, it may do good, and it ought, therefore, never to be omitted."

ON THE FORMATION OF ARTIFICIAL ANUS IN ADULTS,

FOR THE RELIEF OF RETENTION OF THE
FÆCES.

By JOHN ERICHSEN, Esq.

[Concluded from p. 192.]

(For the *London Medical Gazette*.)

THE following are the cases which require the formation of an artificial anus:—

1st. Stercoral tympanitis produced by obstruction of the rectum, or of the sigmoid flexure of the colon. Whether this obstruction be the consequence of disease of the intestine itself, or of any of the neighbouring parts, provided we cannot overcome the obstacle from below, and that life consequently is in danger, an artificial anus must be established.

2d. Simple retention of the fæces producing a stercoral tympanitis, which cannot be relieved, and which endangers life.

3d. Scirrhus affections of the rectum, as soon as there is much difficulty in defecation. The establishment of an artificial anus is, in these cases, the only means of retarding the progress of the disease.

4th. Imperforate anus, or rather the absence of a portion of the rectum, when the passage cannot be established in its natural situation.

Amussat states that during his practice he has seen at least seven or eight patients die of stercoral tympanitis, in consequence of his not having dared, in accordance with the views of most surgeons, to open the obstructed bowel.

It was whilst attending Broussais, who died of obstruction to the passage of the fæces, produced by a scirrhus disease of the rectum, that Amussat was led to reflect on the best means of relief in similar cases, and he determined upon putting his project, of opening the colon from the left lumbar region, into execution, as soon as he had an opportunity of so doing; and for this he had not to wait long, as two cases soon occurred to him which fully justified the performance of this operation.

CASE I.—Madame Dubois, aged 48, of a sanguineo-nervous temperament,

had been for several years subject to constipation, her stools being painful, and occurring at intervals of seven or eight days. She has been in the constant habit of using clysters. She always had the appearance of good health, and all her functions were well performed, with the exception of the act of defecation. About the beginning of May, 1839, she was attacked with most obstinate constipation: clysters, baths, and the most powerful purgatives, failed in producing any effect. M. Amussat, who was called in on the 29th, examined the rectum, with a view to remove hardened feces, which he thought were probably lodged there, but he found the intestine empty. At this time the patient suffered dreadful pains in the bowels, and uttered the most piercing cries, as if she were in labour. There had been no alvine evacuation for twenty-six days, but the desire to go to stool was incessant. Amussat again examined the rectum more carefully than before, and, after a good deal of difficulty, found that, at the upper part of this gut, there existed a round hard tumor, about the size of an orange, and not very moveable; it appeared to be connected with the anterior wall of the sacrum, and completely obstructed all passage through the rectum. The mechanical nature of the obstacle being thus ascertained, it was determined to operate. Accordingly, the 2d of June was fixed for the day of operation, at which Amussat invited me to attend. At this time the patient was labouring under the following symptoms, which closely resembled those of strangulated hernia. She had nausea, with almost constant vomiting and hiccough: the abdomen was painful on pressure, and enormously distended, its circumference being nearly doubled; the face was red and injected; thirst great: anxiety extreme; and she uttered the most piercing cries, calling out for some operation for her relief.

The patient having been laid on her face, with the body inclined somewhat to the right, two or three cushions were placed under the abdomen, so as to raise the left lumbar region. The operation was then performed in the manner that has already been fully described. When the colon, which was reached without any difficulty, was punctured, an immense quantity of gas

and liquid feces spirted out in a jet; there being sufficient to fill three large wash-hand basins. Injections of warm water were then made in both directions along the intestine, and brought away a large quantity of more consistent feces, which were covered with a thick mucus: the intestine was then drawn forward by three spring artery forceps, by which the sides of the incision in it had been held open whilst its contents were discharging, and fixed to the sides of the incision in the skin, by means of four points of interrupted suture: only two small arterial branches were divided, the hæmorrhage from which was readily arrested by torsion*. The patient expressed herself greatly relieved immediately after the operation, and said that she felt more comfortable than she had done for several weeks previously. She was then cleaned and put to bed, a poultice having been applied to the wound.

In the after-treatment nothing of consequence occurred; on the 13th of July she was sufficiently well to be able to go into the country. The stools, which were at first glairy, liquid, and abundant, soon became more consistent and regular. The feces, which are figured, are readily retained by a compress and bandage, so that the patient is not in the least offensive either to herself or to her friends. There is an interesting fact connected with this case, which throws some light upon the physiology of the rectum, namely, that the motions, although figured, and having the same appearance as those which were voided by the natural passage, have little or no fecal odour.

Five months after the operation the patient was in an extremely good state of health; her complexion was clear, and she had not the appearance of one suffering from any malignant disease; so that probably the tumor in the pelvis, which appears in every respect to be stationary, is of a simple nature. The appetite is better than before the operation, probably because digestion is more rapid, and because

* I may mention incidentally, that Amussat has informed me that he has employed torsion of the femoral artery seven times in amputations of the thigh; of the axillary once, in amputation at the shoulder-joint, and of the brachial, several times, in amputation of the arm, with complete success.

the excrementitious matters remain a shorter time in the intestines.

The inconvenience of the artificial anus is very trifling; much less so than would, *a priori*, be supposed: when the patient forces, or makes any effort, the mucous membrane has a tendency to protrude: this, however, can easily be returned, by means of slight pressure exerted by a compress and bandage.

CASE II.—Mr. T., *ætat.* 62, has for several years suffered from painful and difficult defecation, the fæces being very fœtid, and mixed with purulent and ichorous matters. This state having continued for three years, he became exceedingly emaciated, and when the stools came away he felt excessively exhausted and faint.

On examination, it was found that he had a carcinomatous affection of the upper part of the rectum, consisting of scirrhus vegetations, arising from the inner surface of that intestine, and nearly blocking up its cavity. The finger could be made to pass into the constricted part, but could not reach its upper termination; below there was a prominent ring, feeling like the neck of the uterus, largely opened and cancerous.

It was determined, in consultation, to attempt to break down the tumor: this was done with long forceps, which crushed and pinched its most prominent part; cold water was then injected, in order to keep down inflammation: this was repeated several times, and a considerable portion of the tumor was thus removed. Cauterizations with caustic potass were then had recourse to, and were repeated several times, at intervals of three or four days; by these means the tumor was diminished to half its original size. However, the patient's condition grew most alarming; he had no stools for twelve days, and then with such violence as to lower him till he fainted. His emaciation was extreme, and the symptoms altogether so serious, that, in order to save him from a speedy death, it became necessary to adopt any resource that surgery might offer. The operation for artificial anus, which had lately been performed on the preceding case with success, suggested itself as presenting a double object—namely, in the first place, to relieve the retention of the fæces, and secondly,

to prevent their injurious action on the diseased intestine.

Accordingly, on the 14th of July, 1839, the patient not having had a stool for eight days, the operation was performed. It was begun in the way that has already been described; but when the operator had dissected through the celluloso-adipose tissue covering the peritoneum and intestines, he found that he was too much to the outer side, and that the colon, being strongly retracted upon itself, was concealed under the *quadratus lumborum*: it thus became necessary to cut across some of the fibres of this muscle, and then, the intestine having been seized with the usual precautions, which have been already described, was incised in the posterior third of its circumference: nothing came away at first but gases, and a few balls of fecal matter, and it was not until the fourth day after the operation that the contents of the bowels were freely discharged through the artificial anus. As the aperture in the lumbar region evinced some disposition to close, it was necessary to keep it open with tents and sponges. The health of the patient gradually improved, and in a month after the operation he was able to leave for the country. His appearance was at this time greatly changed for the better; his complexion had become clearer, his appetite had returned, and all the functions were well performed; there was no longer any tympanitis, or forced retention of the fæces, regular and figured motions being passed by the artificial anus. The disease of the rectum had somewhat improved, having lost its granular and vegetative feel; if, however, it should retrograde, it will not, as long as it is confined to the rectum, compromise the life of the patient, but if it extend beyond these limits, of course his condition will be altered.

The opening of the artificial anus is now (four months after the operation) rounded, and the mucous membrane is deeply seated: this opening has a great tendency to contract, but it can readily be dilated by tents and prepared sponges.

It is usually said that an artificial anus is a very disgusting and loathsome infirmity; but it is necessary to distinguish between the different kinds

of artificial anus, and also to take into account their situation: for it is evident that an accidental artificial anus, the consequence of a hernia or of a wound, being generally situated in the small intestines, the results of defecation will, in such a case, be very different from those that are observed when an artificial anus is established in the large intestine: so, likewise, an

artificial anus, situated towards the front of the body, will be more disgusting than one situated posteriorly. In the two patients whose cases have been just related, a simple bandage and compress were fully sufficient to retain most completely the contents of the bowels, which were solid, and possessed but little odour.

Table of the Eight Operations for Artificial Anus on Adults.

| Date of Operation. | Name of Operator. | Sex. | Age. | Nature of the Case. | Nature of the Operation. | Result. |
|--------------------|-------------------|--------|------|-------------------------------------------------------|----------------------------------------------------|-----------------------------------------------|
| 1776 | Pillore. | Man. | — | Stricture of the rectum. | Incision in right iliac region to reach the cæcum. | Death 28 days after the operation. |
| 1797 | Fine. | Woman. | 63 | Scirrhus of the rectum. | In the umbilical region. | Death in 3½ months. |
| 1818 | Freer. | Man. | 47 | Stricture of the rectum. | Littre's operation. | Death in 8 days. |
| 1820 | Pring. | Woman. | 64 | Stricture of the rectum. | Littre's. | Was living 5 or 6 months after the operation. |
| 1824 | Martland. | Man. | 44 | Stricture of the rectum. | Littre's. | Was living a year after the operation. |
| 1839 | Amussat. | Woman. | 48 | Obstruction of the rectum from a tumor in the pelvis. | Callisen's, modified. | Living. |
| 1839 | Amussat. | Man. | 62 | Scirrhus of the rectum. | Callisen's, modified. | Living. |
| 1839 | Velpeau. | Woman. | 70 | Scirrhus of the rectum. | Littre's. | Death in 2 days. |

It will be seen by the accompanying table, that eight operations for artificial anus have been performed on the adult. Although Littre had, in 1710, proposed opening the intestines in cases of obstruction of the rectum, it was not until the year 1776 that his proposal was carried out by Pillore, who was the first to perform any operation of this kind. It will also be seen by the table, that four men and four women have been the subjects of operation: in all of them the disease for which the operation was performed was an obstruction of the upper part of the rectum, or of the lower end of the sigmoid flexure of the colon, probably of a scirrhus nature.

With regard to the operative proceedings that have been employed:—Pillore opened the cæcum from the right iliac region. Freer, Pring, and Martland, adopted Littre's method, as modified by Duret, namely, opening

the small intestine from the left iliac region. Fine, of Geneva, opened the colon immediately below the umbilicus. Velpeau performed Littre's operation, somewhat modified by himself; and Amussat, in his two cases, opened the colon from behind, in the left lumbar region.

Thus, of the eight operations for artificial anus performed on the adult, we find that in six the peritoneum was opened: of these six cases, three died of peritonitis, in consequence of the operation; whilst the two cases in which the peritoneum was not wounded have been completely successful. Although these numbers are too small to warrant any general deductions, they are nevertheless highly satisfactory.

The following are some of the conclusions that Amussat comes to:—

1st. The idea of opening the colon in the left lumbar region is not new; but the unsuccessful trials of Callisen

and of Duret on the bodies of children had caused it to be rejected.

2d. Trials on the dead body carefully conducted, prove, however, that the operation is practicable, simple and easy of performance, and that it is founded on positive anatomical facts.

3d. The transverse incision which Amussat adopts in preference to the longitudinal one of Callisen facilitates the operation, and allows us to establish the artificial anus somewhat to the side, and not altogether behind. It thus possesses the triple advantage of facilitating the search for the intestine, of allowing the anus to be made a little more to the side, the patient being thus better able to adjust any retentive apparatus that he may employ, and of enabling the surgeon to avoid wounding the peritoneum.

4th. It is of the greatest importance that the intestine, after having been opened, should be drawn well forwards and firmly fixed to the incision in the skin, by means of sutures, so as to prevent effusions into the loose cellular tissue of the wound.

5th. The artificial anus is a much less disgusting infirmity than would *a priori* be supposed.

6th. Reasoning and fact prove incontestibly, that the preference should be given to Callisen's operation as modified by Amussat.

ON CONGENITAL OPACITY OF THE CORNEA.

To the Editor of the Medical Gazette.

SIR,

WHILE on a recent visit to Aberdeenshire, I was requested by Mr. Proctor, surgeon, Towie, to visit, along with him, a child of three months of age who had been born blind. On examining the eyes the corneæ were found to be of a pearly or bluish-white colour, deeper and more opaque at their centres than their circumferences. The irides were indistinctly seen through them, and, although the pupils were dilated and irregular in form, it was evident from their sluggish motions that they were sensible to the stimulus of light. Both eyes appeared to be small, flat, and undeveloped, and were in a continued state of oscillation. Mr. Proctor and the mother of the child

said they were then considerably clearer than they were at birth. The eyes and their appendages were perfectly healthy, and stated to have been so since birth, at which time the opacity was first discovered by the nurse.

Mr. S. Crompton, in the *MEDICAL GAZETTE* of the 12th of December last, records several instances of congenital opacity of the cornea that have occurred both in his own practice and in that of others, particularly in that of Mr. S. Farar, of Deptford; to the two first of which that above related agrees in almost all particulars.

Mr. Middlemore, of Birmingham, it would appear, doubts the occurrence of congenital opacity of the cornea, but the cases now on record, although few in number, leave no question as to the possibility of such an event, and the veracity of Messrs. Crompton, Walker, and Barton*, cannot be called in question, however it may run counter to the preconceived notions of Mr. Middlemore, high as is his authority in ophthalmic surgery. Assuming, then, that congenital opacity of the cornea may, and has more than once existed beyond the possibility of doubt, it appears to me that its occurrence may be explained by three causes, all different in their nature and effects. In the two cases recorded by Mr. Crompton, as occurring under his own eye, Messrs. Allen and Barton agree with him in regarding the eye as in an undeveloped state, and in the instance which I have related it was one of the most obvious conditions. Mr. Farar, however, does not say whether in the instances that fell under his observation the eyes were in this state; he merely notices the opacity of the cornea; but from their similarity to those already spoken of, so far as can be learned from his paper as quoted by Mr. Crompton, it is not unfair to infer that they were of the same nature; the opacity originating in the same cause—arrested development. The fœtus, we know, is subject to many diseases in utero, and arrest of development of one or other of its organs is a matter of every-day observation. On what grounds, then, can the eye be exempted from the same laws as frequently influence the other organs of the body? and if this is granted, why deny its

* Vide Mr. Crompton's paper in *MED. GAZ.* Dec. 12, 1840.

influence, or reject it when obvious as a sufficient cause of congenital opacity of the cornea?

Mr. Crompton also quotes a case from Mr. Walker, of Manchester, in which, on the second or third day after birth, the cornea were found to be "opaque throughout, and unusually large and prominent, so that very little of the sclerotic was discernible." The opacity was of a bluish white colour: there was scarcely any irritation about either eye: nothing like inflammation;" but in the second year the cornea were "perfectly transparent, and of normal size." It is at once obvious in this case, although there were opaque cornea, that the condition of the eye was different from that in the cases already commented on. And, if together with the appearance of the eyes, we take the satisfactory progress of the case, so that in two years complete vision was restored, we are led to conclude that the opacity resulted from a redundancy of the aqueous humour, not from congenital arrestment of the development of the eyes.

The due amount of the aqueous humour evidently depends on a happy balance being struck between the functions of its-secreting and absorbing organs: hence the *rationale* of the production of the opacity in this instance is easily understood. The function of absorption of this humour being impaired, whilst that of its secretion continued normal, opacity of the cornea, from over distension of the anterior chamber, was the result.

Again, in another quotation from Mr. Walker given by Mr. Crompton, a case is detailed where there is every reason to believe that purulent ophthalmia, ending in destruction of one eye, and great impairment of vision in the other, had run its course in utero. This, although hitherto an unnoticed occurrence, cannot be denied, resting as it does on so respectable evidence as that of Messrs. Crompton and Walker. Intra-uterine pathology is but in its infancy, yet the researches of Graetzer, Simpson, and others, have revealed enough to make us cease to wonder, as year after year witnesses new contributions to this department of pathology, which overturn and root out opinions and dogmas that have "grown with our growth and strengthened with our mind."

From what has been said I would infer, as already stated, that congenital opacity of the cornea may occur in three ways:

1st. From arrested development of the eye.

2d. From loss of balance between the functions of secretion and absorption of the aqueous humour, occasioning over-distension of the anterior chamber of the eye, and consequent opacity of the cornea.

3d. From intra-uterine purulent inflammation of the eye.—I am, sir,

Your obedient servant,

JOHN CHRISTIE, M.R.C.S.L.

50, North Hanover Street,
Glasgow, April 12, 1841.

CASES OF CLUB-FOOT, WITH A FEW OBSERVATIONS THEREON.

By EDWARD WEIGHT, M.R.C.S., &c.

Surgeon of the Wokingham Union, and formerly Clinical-Assistant at the Westminster Hospital.

[For the Medical Gazette.]

THE Editor of the MEDICAL GAZETTE having been kind enough, in January of last year, to publish an account of a few cases of talipes treated by me, as well as some reflections that occurred to me after a careful consideration of the facts then presented to my notice, I am induced again to trespass a little on the patience of the readers of the GAZETTE, and transmit an account of two cases, together with a few observations, which my further experience has suggested.

CASE I.—Mr. H——, aged 18 years, was born with varus. He was for several years under the care of a mechanist of high repute, by whom the deformity was relieved to a certain extent. When the patient applied to me, the heel was two inches from the ground; the tarsus much arched; the convexity projecting much outwards, not forwards, as in pure talipes. The dorsum, especially over the os cuboides, was covered with a thickened cuticle, indicating the part where formerly rested the weight of the body. The affected foot was altogether smaller in size than the sound one. He now rests his entire weight on the metatarsal bone of the little toe. The entire limb is shorter and more delicate than the healthy. The tendo-achillis is thick-

ened: the inner edge of the plantar fascia prominent and rigid. There is motion between all the tarsal joints. The circulation in the foot is feeble, and the toes are always cold.

April 1st, 1840.—In the presence of Messrs. George May and Bulley, of the Reading Hospital, and of my neighbour Mr. Taylor, I divided the tendo-achillis in the usual way.

4th.—The wound being healed, Stromeyer's board is applied.

9th.—He suffers great pain at the sole of the foot, from the foot-board. The foot can be bent to nearly a right angle with the leg.

15th.—The pain arising from the pressure of the instrument is relieved by the use of air-pads.

16th.—Little's modified Scarpa-shoe was applied yesterday instead of Stromeyer's board, and to-day the patient complains that pain is produced after a little walking. The plantar fascia is very tense, and appears to impede the complete flexure of the foot.

May 5th.—With the assistance of my friend Mr. Bulley I divided the inner edge of the plantar fascia.

I was induced to make this additional section by experiencing a difficulty in moving the foot upwards and outwards. It appeared to me that the plantar fascia was the sole obstacle. He had the power of abducting the foot without producing tension of the adductors. Hence I do not attribute the existing incurvation to the contraction of the tibialis anticus, tibialis posticus, or flexor longus pollicis, but to the deficient length of the plantar fascia. The little wound is covered with a piece of sticking-plaster, and the patient is placed in bed.

7th.—Stromeyer's board is applied to-day.

9th.—He stands more evenly on the os calcis. Little's boot is applied, and he walks about more freely.

18th.—The weight of the body tends too much to the outside of the foot.

June 5th.—The tarsal arch is improved.

January, 1841.—Stromeyer's board has been discontinued for some time. The patient favours the affected limb, and says it is weaker than its fellow. Within the previous four months it has very much increased in point of strength and size.

In this case the mechanical contri-

vances which were employed were successful in overcoming the varus almost entirely, but the operation of Thilenius alone was sufficient to bring down the heel. The patient is now employed in agricultural pursuits. He cannot stand upon the affected limb alone more than a few minutes without support. The flexion of the joint is perfect. The foot has increased in length and in breadth, and it is altogether normal in shape, and, upon the whole, the error of his gait is hardly perceptible.

CASE II.—William Hook, *at.* 36, a healthy subject, was born with well-formed feet, and when about three years old was trodden upon by a horse: after this the contraction occurred.

The dorsum of the foot was, when he applied to me, much arched. The astragalus projected considerably. A deep furrow extended across the sole of the foot; the extremities of the metatarsal bones and the os calcis being drawn close together; that is, not more than two inches apart. The heel was raised four inches, and there was no apparent want of power in the muscular apparatus of the foot.

April 1st, 1840.—In the presence of the friends whose names are mentioned in the history of the last case, the tendo-achillis and the plantar fascia were divided in the ordinary way. Sticking-plaster, pasteboard splints, and bandages, were applied.

4th.—The wounds have cicatrized. Stromeyer's board applied.

9th.—The heel is considerably lower, and the arch of the tarsus suppressed. He bears the board without much uneasiness.

May 1st.—The foot may now be brought to a right angle with the leg. He can place the foot flat on the ground.

3d.—The great toe being in a state of permanent extension, I divided the extensor muscle.

6th.—I have had a strong spring placed on the sole of Little's boot, the action of which tends to promote flexion of the foot, whether the patient be recumbent or perpendicular.

8th.—The flexion of the great toe is now permitted.

June 18th.—The patient's gait is much improved. The sole of the foot is nearly of its normal flatness. He wears a laced-up boot with a cork sole.

July 10th.—The foot is now nearly

natural in its appearance, and he can walk about the whole day without pain.

REMARKS.—In my former communication I was led to observe that “too favourable an impression of the facility of this operation, and the celerity of the cure, had been conveyed to the public, and I did not, therefore, feel justified in keeping in the shade the difficulties and delays which inevitably occur in the management of these deformities by operation.” My subsequent experience has tended to confirm me in the opinion which I then expressed. I feel convinced that many cases have been undertaken which were not susceptible of improvement by surgical treatment, and that too great results have been expected in *all* cases.

When the age of the patient is somewhat advanced, and the deformity aggravated, no benefit can reasonably be expected from this operation, unless the patient possess an excellent constitution, great intelligence and power of endurance, and an unlimited amount of time at his disposal.

In all the cases of this malady, there can now be no doubt that the muscular power of the antagonist of the contracted muscles is either very much diminished or annihilated, and that even after the restoration of the limb to its proper symmetry, an artificial force must be employed to counteract the preponderant action of the contracted muscles. I understand that Dr. Little and his colleagues now adopt this plan in every case.

Although I do not choose to blink the difficulties which constantly occur in the treatment of these cases, I am far from wishing to detract from the real merits of the operation. It is without doubt well adapted to relieve to a greater or less degree a great variety of deformities, and will prove a blessing of great value to the rising generation.

A great many requisites are demanded for the general success of this therapeutic scheme. Expensive apparatus, intelligent attendants, time and patience, are indispensable in all cases; and in many instances the want of these has precluded the adoption of this means of cure. I have had the good fortune to act under an exceedingly liberal and humane Board of Guardians, who have, without stint, supplied me with every thing I required for the

treatment of my pauper cases. But I fear few of my professional brethren are likely to meet with equal encouragement in this respect. I think it therefore a matter of congratulation that an orthopedic hospital has been established, where all the means which science can suggest are supplied for the use of patients afflicted with deformities. I think that the institution has a claim for a subscription from every parish in the kingdom in which a club-foot or deformed limb may be found. It ought not to excite jealousy in the regular hospitals, since the cases it undertakes require a minuteness of attention on the part of the medical attendants which is not to be expected, because it is impracticable, at these institutions. Such an institution, if well conducted, would not in its beneficial influence be restricted to the poor alone. The improved modes of treatment to which it would give rise would be directly applicable also to the relief of the afflicted amongst the wealthy.

Wokingham, Berkshire,
April 2, 1841.

MEDICAL GAZETTE.

Friday, April 30, 1841.

“Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso.”
CICERO.

MANAGEMENT OF THE POOR IN SCOTLAND.

SOME subjects, says Horace, will please but once, while others will gratify the reader or spectator, though repeated ten times*. Scarcely any topic will bear frequent discussion with more advantage than the one which we have placed at the head of this article—a topic which involves the happiness of a nation, and is alike interesting to the physician, the statesman, and the philosopher. Such a subject, if handled with ordinary skill, must excite the attention of every man not destitute of

* *Hæc placuit semel; hæc decies repetita placebit.*

human sympathies; what must it effect, then, when discussed by a writer like Dr. Alison, whose good sense kindles into life under the breath of good feeling, and in whose hands dry figures, no longer inanimate, are made to speak the language of humanity and religion?

Besides those capital essays which, on former occasions, have been the subject of our commentary, Dr. Alison has more lately published a summary of his views in a pamphlet of forty-seven pages†.

It is extracted from the Quarterly Journal of the Statistical Society of London, and will, we trust, have a circulation as great as its merits.

Some points are, of course, brought out more prominently in this than in the former essays; but the subject gains by this alternation of interest; for truth may be looked at, with advantage, in a variety of lights.

A singular circumstance, and well worthy of note, is, that the Scottish law, in theory, is humane; it is the practice only which has left the misery of the indigent unrelieved. This neglect has been carried to such a pitch that, in many places, "the allowance they receive can be regarded as nothing else than a *system of protracted starvation*." These words are extracted from a report made in the town of St. Andrew's by a committee consisting of the Provost and three members of council, Sir David Brewster, the episcopal and two dissenting ministers, &c., and unanimously approved by the Town Council. They are speaking, indeed, of their own town only; but, unfortunately, the reproach applies to Scotland generally. More than half the permanent paupers receive an allowance of one shilling a week each,

to provide themselves with food, clothing, fuel, and lodging. If this is not a mockery of relief we do not know what is. The poor wretches waste away under the infliction of their innutritious diet; and "their feeble attenuated appearance bears sufficient testimony to the inadequate manner in which they are supplied with the necessaries of life." In plain English, they are starved, and look starved.

In the small town of Tranent, matters are just in the same state. A shilling a week is the usual pension for the old age of those whose youth and strength have been spent in serving the community. They would die of cold and hunger did not benevolent persons, *generally working people*, assist them with money and food. Suppose a collier to be reduced by disease or accident, does society lend him a helping hand? Hear Dr. Somerville Alison. "So urgent is their distress, that many of them, even in this frail state, go out to the colliery and do a little work. *I have known men so situated work occasionally to within a day or two of their death*; and have little doubt the lives of many are thus shortened." Does not this sound like an account of the condition of negroes on a bad estate, in the worst times?

Mr. Barclay, the Sheriff Substitute of Perthshire, last year drew up some observations on vagrancy, which do honour alike to his head and heart. The distinction, indeed, which is commonly made between those sentiments which are the offspring of pure reason, and those which are the effusion of benevolence, is often a groundless one, and separates what is naturally intermingled. The cold economist who reasons algebraically on the progress of population, and calculates happiness by logarithms, is apt to make more foolish deductions than a child ten years old; while more genial lawgivers, sympathizing with the

† Illustrations of the Practical Operation of the Scottish System of Management of the Poor. By W. P. Alison, M.D. &c. [Read before the Statistical Section of the British Association, 18th Sept. 1840.]

hopes and joys of their fellow-creatures, and without dread of the multiplication of mouths, have arrived at truer conclusions, and established the frame of society on a firmer basis, than the most subtle analysts.

Mr. Barclay is well aware, that to sweep indigence from the face of the earth is a scheme merely fit for a stark-mad economist, who sees the world only on paper. It is just barely possible—and hardly so, we should hope—to sweep it away from the sight of the rich. To pretend to relieve the pauper with a shilling a week, and then hunt him back to his hovel, if he appeals to the kindness of his neighbours for real relief, is so shocking to the common sense of mankind, that, though often tried, it never succeeds in any age or country. It was in vain that Henry VIII. and his successors tried martial law and executions on the largest scale; the excesses caused by misery are stopped by relief, not punishment. English indigence was softened, like the traveller in the fable, by the sun, and not the storm; the 43d of Elizabeth succeeded, where the provost-martial had failed.

Mr. Barclay mentions a county (Perthshire, we suppose) where vagrancy and crime have attained such a pitch, that it is difficult “to reside in the country districts with peace and safety, not to speak of enjoyment.” Curiously enough, some people attribute the evil to begging, and this again to indiscriminate charity, as if nature had forbidden these reasoners to see an inch beyond the surface. This enormous vagrancy, so strange to English ears, is caused by the “very stinted parochial relief given to those on the Scotch poor’s list.” To the unspeakable astonishment of many prosperous gentlemen, the poor cannot live on a shilling a week, and will not die. There is a well-known story of a Frenchman who

on being asked by a minister of state what could have induced him to write a certain infamous lampoon, answered *Monsieur, il faut vivre*. To which the minister replied, *Je n’en vois pas la nécessité*. The gentry of these uncomfortable country districts would seem to have been smitten with the same blindness as the minister in the story; they cannot see why unemployed rustics should refuse to starve quietly on their weekly twelpence, and they condemn the criminal benevolence of those who encourage these annuitants in their expiscatory wanderings. We wish these economists would just turn to the History of England, A.D. 1540—1600, and learn the consequences of leaving the poor to their own resources, as it is termed in Malthusian cant; in other words, to famine and fever. They will easily see that justice is the best policy, and that benevolence to the poor is the best security for the rich. We are glad to find that at this end of the island, the cold paroxysm of Malthusianism, under which so many laboured a few years since, is fast passing away, and that truth, decency, and good feeling, are regaining much of their lost ground. Thus, the Morning Chronicle, a Whig oracle of no mean note, confessed, about a fortnight ago, that it was absurd to expect an agricultural labourer to lay by a provision for his old age, from his scanty wages; and that it was cruel to shut him up in a workhouse at sixty, instead of giving him out-door relief, after he had added considerably by his labour to the capital of his country. Other similar confessions from economic quarters, as well as the turn of the late poor-law debates in Parliament, give the friends of humanity the best grounds for hope. It is to be expected that we shall not much longer hear the mean threat that the ploughman, who has saved nothing

from his wages of eight shillings a week, shall be condemned to pass his last years in the dismal shades of a Union workhouse. It is said, or *was* said, by certain scribblers, that the man who saved up nothing when young was not entitled to an annuity when old. But these purblind sophists forgot that the labourer's wages do not really represent the value of his labour to society; and that if every ploughman who lived to sixty had a pension of ten pounds a year, the community would still be a great gainer by its bargains with the race.

Mr. Barclay concedes too much, we think, when he says, "In England it may be that the pauper is (or at least *was*) in a situation more enviable than the labourer, and so industry was fast merging into pauperism."

The pauper in a workhouse never was in a more enviable state than the labourer at large. To prove this, it is not requisite to weigh their several portions of bacon in the critical balance, and show which of the two lived on the scantiest fare. The confinement and discipline of a workhouse always turned the scale against the pauper; so that a run upon a workhouse, and the desertion of hard-earned potatoes for eleemosynary soup, were never yet heard of, save in the morbid dream of a Malthusian. To go to prison in order to improve one's diet is so rare a whim, that no laws are requisite to guard against it. Nor was "industry fast merging into pauperism." The southern countries of England have often been described in the most moving terms as the very hot-bed of pauperism; nay, M. le Vicomte Villeneuve de Bargemont, formerly Counsellor of State, and *Préfet du Nord*, attributes the excess of poverty in the north of France to the proximity of England, which, he says, has inoculated the rest of Europe with *le*

*véritable pauperisme**. Any one, at a distance, might imagine from these piteous complaints that paupers had eaten up the south of England, like a flight of locusts; and that the labourers having discovered the charms of gratuitous broth, had left the land to produce its own crops. Yet neither Kent nor Sussex has been a wilderness within our memory, but both have always looked more like gardens than deserts; so that the case seems to resemble Swift's story of the nobleman of Lagado (under the Flying Island), whose estate was exquisitely cultivated, but who was ridiculed and despised by his countrymen "for managing his affairs no better, and setting so ill an example to the kingdom."

We are delighted to have occasion again to thank Dr. Alison for his services to humanity, and to find that the clearness with which he states his case is equalled by the perseverance with which he advocates it.

DR. ELLIOTSON AND HIS PUPILS.

"SUPERB and doubly honourable presentation of plate from the grateful and admiring students to the eminent and magnanimous Professor."—Such are the grandiloquent terms in which the above fact is announced in one of the evening papers, and, taken with the manner in which it is printed (the whole being in capitals) they tend to produce a very imposing effect.

In plain language the facts are, that on the 17th a deputation from Dr. Elliotson's pupils, at University College, waited upon that gentleman, and presented him with a handsome piece of plate, in testimony of their admiration of his zeal and talents. To their address Dr. Elliotson made a reply at some length, which has been published with his signature attached, and which we therefore presume to be correct. The most re-

* Alison, Illustrations, p. 37.

markable passage is one referring to phrenology and animal magnetism, on which subjects the Doctor's opinions remain unchanged, as will appear from the following extract:—

"Gentlemen,—This is the most gratifying day of my existence. . . . In advocating phrenology as I have done for nearly five-and-twenty years, and mesmerism as I have done for three years, I have adhered strictly to facts, and so shunned all speculation that those phrenologists who are more prone to listen to authority, and more prone to speculate than to examine nature, regard me as little advanced in phrenological knowledge; and many mesmerists pronounce me a sceptic; and, indeed, the facts are so wonderful and unlooked for, that I have affirmed none, and will affirm none, which I have not myself satisfactorily witnessed, however high the authority that declares them. Phrenology has now at least twenty thousand supporters in this country; and mesmerism is daily gaining ground among able and scientific persons, and is undergoing investigation in very many quarters."

CLINICAL LECTURE,

Delivered at University College Hospital.

By SAMUEL COOPER, Esq.

Senior Surgeon to the Hospital, &c.

GENTLEMEN,—It seems to me, that, in the generality of works on surgery, you will not find the diffused popliteal aneurism described with all that care and accuracy which the importance of the subject demands. On this account I am glad to avail myself of the opportunity, which the case of Jeremiah Tomkins affords, to call your attention to the diagnosis and treatment of a form of aneurism which is often followed by the loss of the patient's limb, or life.

CASE I.—*Diffused popliteal aneurism.*

Jeremiah Tomkins, æt. 35, admitted under Mr. Quain, Oct. 15, 1841: a labourer in the coal trade, and accustomed to drink freely.

About five weeks previously he first noticed a swelling towards the inner and back part of the thigh, and about the junction of the middle with the lower third of this part of the limb. It throbbed and was tender, notwithstanding which he did not desist from work until a fortnight before his admission.

The swelling continuing to increase, he now felt pain in his knee, extending down the back of his leg to the ankle and foot, and also up to the hip.

Three days ago, he observed an increase in the swelling of the parts about the knee, especially in the popliteal space, but extending down to the ankle and foot, and attended with numbness and inability to move the leg.

The following was the state of the case on the patient's admission. In the popliteal space, or rather just above this, and over the course of the femoral artery, was a hard firm moveable mass, discoloured over a portion of its surface, and marked by enlarged superficial veins. The patient experienced throbbing pain in it; the leg was considerably swollen, the foot benumbed, and the knee, which was stiff, was the seat of a pricking sensation. The patient, before his entrance to the hospital, had been salivated, on the supposition that his complaint was rheumatism. The patient, still imagining that his disease was rheumatism, placed himself under Dr. Williams, but was transferred to the care of Mr. Quain on the 17th, as soon as the case had been ascertained to be a secondary diffused aneurism. The original circumscribed aneurism was situated at the commencement of the popliteal artery, and the swelling of the limb below this point, and especially in the popliteal space, had augmented very much during the last two days. The tumor, which was tender, and painful on pressure, could be felt with the hand to be attended with a weak pulsation in it, and I observed some livid discolouration of its surface. When the leg was touched, or pinched, the patient was scarcely conscious of what was done, so great was the degree of numbness in it.

Directly I placed my hands upon the swelling, I remarked to Dr. Taylor and Mr. Morton, who were present when I first saw the case, that its solid feel at once made me certain that the case was not an abscess; and that the view which had already been taken of its true character was the correct one—a point which, had there existed the shadow of a doubt, would have been rendered perfectly clear by the history of the swelling; its throbblings in the early stage of it; its sudden increase when it became diffused, and the reduction in the force of the pulsations accompanying this latter very important change. Then another sign, particularly adverted to by Mr. Morton, was the sensation imparted to the surgeon's hand when it was applied to the swelling, at the moment of pressure being removed from the artery in the groin; for then the fresh and sudden rush of blood to the tumor could be distinctly perceived in it, leaving no doubt of the swelling arising from, and communicat-

ing with, the artery. This is one criterion which, when the pulsation is feeble and obscure, deserves well to be remembered, though I do not know that any distinct notice has been taken of it in works of surgery, with reference to aneurism attended with extravasation of blood. Yet it is a circumstance of great value in elucidating the diagnosis.

For reasons which I shall presently explain, a popliteal aneurism in this stage is one that does not admit of delay, and therefore, after a few minutes' consultation, the operation of tying the femoral artery was performed by Mr. Quain, at one o'clock.

The first incision began about two inches below Poupart's ligament, and was continued downwards three inches. As the lower part of the wound exposed some of the effused blood, the artery was dissected down to in the higher part of it; and the fascia lata and sheath of the artery having been opened, the ligature was applied. The man was afterwards removed to bed; and the limb having been placed on an oblique plane, so as to facilitate the return of the venous blood, it was next covered with blankets, to maintain its temperature and promote the circulation.

As soon as the oozing of blood had ceased, the wound was closed with sutures and isin-glass plaster.

18th.—Temperature of the limb below the aneurismal tumor found to be higher than that of the opposite limb, or than what it had been before the operation. The discolouration from the extravasated blood increased. Pulse 135; no appetite; bowels open; pain in the groin, in the course of the artery, and in the popliteal space, with a pricking sensation in the leg. Tumor less tender.

19th.—Has slept well; pulse 120; general swelling less.

20th.—Edges of the incision nearly united; but there is suppuration in the deeper parts around the artery, some puriform fluid having been pressed out. The temperature of the limb 88 just below the wound, 86 at the sole of the foot, and 90 in the opposite limb.

Some castor-oil prescribed, to open the bowels; and the following medicine, which the patient had been taking, was continued.

R Potassæ Bicar. ʒiv.; Acid Tart. ʒiiss.;
Vin. Ant. Tart. ʒss.; Aq. ʒxij. Ft.
mist. Cochl. magn. ij. alternis horis
sumend.

21st.—Pulse 102: sensibility in the limb somewhat improved; no pain, not even on pressure; tumor diminished.

25th.—(Edema of the leg has disappeared, and the circumference of the thigh, where the aneurism is situated, measures less, by one inch, than on the day of the operation; the

temperature and numbness not altered since last report; discharge from wound lessened.

Nov. 3d.—Ligature came away.

15th.—Limb bandaged, and compress applied over tumor. Swelling decreasing slowly; sensibility of limb perfect again; wound healed; health undisturbed.

25th.—Bandage thought to be serviceable in promoting the absorption of the effused blood.

Nov. 30.—On removing the bandage, a slight discolouration observed over the instep, about the size of a shilling; also two or three smaller spots over the upper part of the tibia. These, it is reported, had certainly been produced by the pressure of the roller.

Limb to be kept more elevated, and all pressure on the discoloured parts to be prevented with pads of lint suitably arranged.

Dec. 5.—The discoloured spots have now become open sores, to which the water dressing is applied. Bandage discontinued.

25th.—Swelling nearly all gone, without further use of bandage. Ulcers healed.

31st.—Bandage has been applied again during the last two days; patient sits up two or three hours daily; a slight hardness the only vestige of the original disease.

Jan. 13, 1841.—Since last report, two sloughs have occurred on the great toe; one on the upper part of it; the other over the tarso-metatarsal articulation; and perhaps ascribable to the effect of the severe weather, as they formed after the bandage had been for some time discontinued. Water dressing applied.

30th.—Slough near extremity of toe has been detached, and the ulcer is left superficial. A portion of the other has also separated.

REMARKS.—This case affords a very good illustration—

1st. Of the symptoms of a diffused popliteal aneurism; the sudden increase of the swelling on the sac giving way; the discolouration of the skin; the solid feel of the tumor, caused by the blood; the numbness and pain in the leg and foot; the œdema; the feeble and obscure pulsations; the thrilling sensation communicated to the surgeon's finger on removing pressure from the artery in the groin: all these points were open to your remark.

2dly. Of the prudence of operating under such circumstances without delay; for if time had been lost, on the old and exploded notion of waiting for the enlargement of the anastomosing vessels, the quantity of blood, effused in the cellular tissue of the limb, would soon have become greatly increased, and the circulation so much impeded from this cause, that gangrene would have been

the consequence, attended with the loss of limb, or even of life. At all events, you may depend upon it, that the risk of the occurrence of mortification is very much in proportion to the extravasation in the cellular tissue, which state, joined to the impediment to the due supply of blood in the leg, caused by the aneurism itself, must be, in every point of view, disadvantageous, and a source of peril. In a case which I attended in private practice, where the effusion of blood into the cellular tissue, from a very large popliteal aneurism, was four times as copious as in this instance, the limb was speedily seized with mortification, and the patient's life was only saved by amputation. Here, indeed, the sac gave way on the side towards the popliteal space; the blood gushed suddenly into the cellular tissue in prodigious quantity, so as to fill and distend nearly the whole of it, from the lower part of the thigh, down to the heel. In fact, there was a large quantity of extravasated blood on each side of the tendon of Achilles.

3dly. The case which you have had the opportunity of studying will also teach you to avoid making pressure on the limb with a tight bandage after the operation; as it is apt, like any thing else that tends to obstruct the free return of blood in the weakened state of the circulation in the limb, following the operation, to cause sloughing and ulceration. Fortunately, in the case before us, such mischief was only superficial, and not of serious consequence. The bandage was applied in consequence of the very slow progress in the absorption of the effused blood. The ulceration produced by it over the tibia and tarsus, however, was confined to a small extent, and of little importance. The most troublesome ulceration occurred near the end of the great toe; but as this came on during the intensely cold weather of January last, and some time after the bandage had been removed, the latter probably had no share whatever in its production. The plan of keeping the limb in a comfortable temperature, and with the foot and leg raised on an inclined plane, to favour the return of venous blood, was, on every account, right and judicious. The decision with which Mr. Quain proceeded to the operation without the least delay, and the skill with which he executed it, were the means of saving both life and limb.

CASE II.—Dislocation of the fifth cervical vertebra on the sixth, without fracture.

You know that a dislocation of the dorsal and lumbar vertebræ, unaccompanied by fracture of the bodies or articulating processes of those bones, is prevented by various anatomical resistances, especially those arising from the size, shape, and direction of the articulating and spinous processes, and the

strength and tightness of the ligaments. But, in the cervical portion of the spine, such an accident is occasionally met with. The complete form of it, however, as distinguished from a displacement of an articular process of one side, is so rare, that the following case well merits your attention.

John Green, aged 51, admitted Dec. 18, at half-past 7, p.m., under the care of Mr. Quain. About 22 hours previously, whilst carrying a sack of coals, he slipped backwards from the step of a door, and his neck came against the edge of the step. The man was unable to rise, his lower extremities being almost completely paralytic; and he felt "sensations of pins and needles" in his upper extremities. The paralysis of the lower limbs increased, and at 12 o'clock, p.m. his breathing became difficult; and, at a later period, he found himself unable to cough. His bowels have not been acted upon: he has been bled twice; and his urine has been drawn off with a catheter.

On admission, he complained of sharp and aching pain about the sixth cervical vertebra; there is no external mark of injury or crepitus to be perceived, and no apparent displacement. His mental faculties are unimpaired; pulse 54, rather full, but soft; respiration 22, and wholly diaphragmatic; he speaks with an effort, his respiration then becoming more hurried, and he is almost unable to cough. His abdomen is somewhat tympanitic. His whole surface is of the natural temperature. The power of sensation in the upper extremities is much impaired, but that of the head and neck, above the clavicles, remains perfect. In descending from this point to about the ninth rib, it becomes less, and is here completely lost; the remaining part of the trunk and lower limbs being wholly paralysed. The loss of sensation extends somewhat higher posteriorly than in front. The loss of motion has a corresponding extent and degree: some power over the movements of the upper extremities still continues, but the man cannot direct them accurately, as if the action of some muscles was completely paralysed. The parietes of the chest, except the diaphragm, are quite immovable. His bladder is not distended. He has no priapism, nor seminal emission. He was placed quietly in bed, and some mild stimulants were administered to him.

9 o'clock.—He is restless, and desirous of changing his position; his breathing more difficult; pulse slower; he is very desirous of drink, which he swallows with facility. In this condition he remained until half-past 4, when his breathing became more difficult, and he passed a very copious stool. He died at half-past 6, 34 hours after the accident.

Examination of the body, ten hours after

death.—No external mark of injury. On cutting down to the cervical vertebræ, some blood was found extravasated between the muscles. The fifth cervical vertebra was found dislocated forwards on the sixth; the articular processes of the former having passed in front of those of the latter. The capacity of the spinal canal was greatly diminished, the cord compressed, and blood effused into its substance. The nerves passing out between the fifth and sixth vertebræ were compressed; the anterior common ligament was stretched, and partially torn; the intervertebral substance was entirely torn from the body of the sixth vertebra; the articular ligaments were lacerated; the supra-spinous was entire, but stretched; the ligamentum subflavum was torn, and partially detached; the blood throughout the body remained fluid, and occupied chiefly the venous system.

The lungs were generally emphysematous in feel and appearance; there were some points of ecchymosis in their substance; and the bronchi contained a great deal of frothy mucus. There were also some spots of punctiform and stellated redness in the course of the intestinal canal.

The particulars now explained, including the symptoms during life, and the post-mortem appearances, cannot fail to interest every student desirous of gaining a knowledge of the accidents to which the spinal column is liable. This is the second example of a complete dislocation of the cervical vertebræ, unaccompanied by fracture, which I have witnessed within the last six or seven years. By the favour of a gentleman, formerly attending my lectures, I was enabled, a few sessions ago, to exhibit to the surgical class of University College a specimen of a complete dislocation of the middle cervical vertebræ, without fracture. The man from whom it was taken was killed instantaneously, by his head being forced against the top of a gateway, as he was sitting on an omnibus, which was going along at a rapid rate. The body was conveyed to the Middlesex Hospital. In the late Mr. Howship's museum might be seen another example of a complete dislocation of the cervical part of the spine without fracture.

COMPOUND CATHETER.

REPLY TO MR. FOULKES AND CHIRURGUS,
BY A PUPIL OF DR. BUCHANAN.

To the Editor of the Medical Gazette.

SIR,

HAVING been a pupil of Dr. Buchanan at the time he had his stricture instrument

constructed, and having been, therefore, upwards of ten years familiar with its form and application, I was certainly not a little surprised at Mr. Foulkes' attempt to pass off that instrument as an invention of the present day and his own. If the principle of the two instruments, merely, had been the same, it would be unfair to call in question Mr. Foulkes' originality; but that he should have lit upon not merely the principle, but the whole details of the construction of Dr. Buchanan's instrument, is somewhat too much to be believed on this side of the border. It is sometimes difficult for a man to find out the origin of his own thoughts; and, without insinuating that Mr. F. owes any thing to the itinerant catheter-maker, I am persuaded that if he will take the trouble to recal his first ideas on this matter, he will find they did not originate solely "in the torture endured by his patients" under the usual treatment: I make this supposition merely that I may not be obliged to bring against any member of a liberal profession a charge so odious as that of deliberate plagiarism; although, I confess, Mr. Foulkes' last letter does not call for much delicacy of reply. The wrath which he manifests is not unlike that of a person who feels sore on being stripped of his borrowed plumes. His abuse of the whole Scotch nation, and his endeavour to enlist the sympathies of all Englishmen on his behalf, are peculiarly absurd. If he had been an Irishman, he certainly would have urged the matter as an additional reason for the repeal of the Union!

Mr. Foulkes denies the identity of the two instruments. There certainly are differences; but every difference is a fault. Mr. Foulkes' instrument is an awkward imitation, by a person who has not thoroughly understood the uses of the original. Thus, his small catheter is imperforate at the point, which deprives him of the use of the silver probe inside. There is a clumsy head-piece on all of the catheters, which prevents their slipping over each other when we wish to withdraw any of the larger pieces, leaving the smaller behind—a most important practical application of the instrument. Correct these defects, and Mr. Foulkes can no longer deny that his instrument of 1841 is in every respect that of Dr. Buchanan's of 1831.

One word to Chirurgus. If he compares M. Gerdy's apparatus and that of Dr. Buchanan, he will find that, while they resemble each other to a certain extent in principle, they differ completely in the details of structure and mode of application. M. Gerdy certainly employs several canulæ passing within each other, *but these canulæ are all of the same length*; the smaller

(cannules de remplissage) being merely intended to fill up the void in the larger, and form a *single conductor*, which guides down to the stricture a small sound or bougie, by which alone the dilatation is effected. How different is this from a series of catheters, of *different lengths*, passing over each other, and all contributing on the principle of the wedge to effect dilatation. Instead of being mere conductors, the larger canulæ are most powerful instruments of dilatation, and by far the safest, for they take the smaller canule, which have passed on beyond them, for their guides, in forcing their way through the stricture. 'Chirurgus' own proposal is liable to the same criticism. I may add farther, that a single conductor, while it is of no use as an instrument of dilatation, does not meet the difficulty presented in the majority of bad cases of stricture, in which there is not one only, but two or three contractions of the urethra. In such cases you must have two or three conductors, of different lengths and diameters, which would form, together, an apparatus on the same principle as Dr. Buchanan's.

I hope my regard for an old teacher will be held motive sufficient for my thus adventuring to break a lance in his just quarrel.

I remain, sir,

Your most obedient servant,

"SICUT CUIQUE."

April 6, 1841.

GUY'S HOSPITAL CLINICAL REPORT SOCIETY.

On Thursday evening, the 22d inst., the tenth general meeting of this society was held in the medical theatre: Bransby B. Cooper, Esq. in the chair.

This society, which is peculiar to Guy's Hospital, was founded by the late lamented Mr. Blackburn, and has been carried on with the most distinguished and almost unexpected success. The object of the society is implied by its name: each member has a certain portion of the Hospital assigned to him, all the cases in which he is bound to report. The members meet weekly, and discuss any remarkable cases which may present themselves.

At the close of each session, the honorary certificate of the society, stamped with the great seal of the Hospital, is awarded to that gentleman whose reports are considered the most perfect.

At the meeting lately held, after the report had been read by Dr. E. L. Birkett, the secretary, *two* honorary certificates were presented; one to J. R. Bedford Esq. late secretary, to whom the society is most deeply indebted; the second to Mr.

D'Anvergne, for the superiority of his reports. The Chairman presented these honourable testimonials, accompanied by most feeling addresses, to each gentleman.

Resolutions were moved and seconded by Messrs. Purchas, Menzies, Pizey, Veasey, Clegg, Gull, Longmore, Noyes, Chapman, and Francis, and the meeting separated, having been conducted and characterized throughout by the utmost harmony of sentiment.

REMARKABLE ŒDEMA IN THE ARM OF A FEMALE,

ALTERNATING WITH THE STATE OF THE
MENSTRUAL DISCHARGE.

DR. POST related a singular case in the N. Y. Hospital of œdema of the right arm in a female, which began three years ago, and was produced by putting it in hot water after it had been very much chilled. This was followed by swelling of the arm, and by cessation of the menses, which were regular before. The elbow became stiff, and she has not been able to bend it since. She has menstruated two or three times since it happened, but never perfectly; and at these periods there was a remarkable diminution of the swelling, so that it nearly disappeared; at other times it is so hard that it will not pit on pressure. There is always an increase of pain and swelling on the approach of the menstrual period. The forearm bears the mark of extensive incisions, the cicatrices being more distended than the sound skin, so as to form cylindrical prominences. Various modes of treatment have been employed. After menstruating last month, the swelling of the forearm nearly subsided. The arm can only be kept with the fingers hanging down when walking, as she is not able to support it in a sling; while sitting, she has it supported on a pillow. She has recently menstruated more freely than at any time previous to her becoming affected, and the swelling has nearly subsided; she has menstruated two months in succession, which had never been the case before since her attack; she had suffered from vomiting, but has now recovered from that. A seton was placed on the back of the wrist a month ago; she had before been partially relieved by an issue. The case is remarkable for the long continuance of the œdema, and for its connection with menstruation.—*New York Journal of Medicine and Surgery.*

REMARKABLE EFFECTS OF RHEUMATISM.

DR. WASHINGTON mentioned an instance of the remarkable effects of rheumatism which he had witnessed in a young man 19 years of age, brother of one of the teachers of the Deaf and Dumb Asylum. He has been suffering from it ten years, and lost a brother who had it the same length of time. His knees are dislocated, so that the condyles of the femur are anterior to the head of the tibia; the bones of the spine are ankylosed; the chin is fixed within two fingers' breadth of the top of the sternum, so that he cannot move his head without moving the whole body; the union of the bony surfaces is apparently perfect. The sight of the right eye has been destroyed by iritis; and the pupil of the other eye is so contracted by the same disease, as to prevent his reading. There is great emaciation of the whole system, and particularly of the limbs, so that his thigh is not larger than the wrist of an ordinary sized man. There is now active disease in both wrists, which are tender, and have a doughy feel. His digestive organs are in good order, his tongue slightly furred. He is of a cheerful disposition, and continued to read as long as the state of his eyes permitted. Dr. W. never saw anything approaching such a degree of deformity.—*New York Journal of Medicine and Surgery.*

LECTURE XXXIII.

Treatment of Tetanus, continued. Wine; mercury; purgatives; digitalis; tobacco; musk; prussic acid; belladonna; carbonate of iron; oil of turpentine; strychnia; surgical expedients; general rules. Hydrophobia.

IN the last lecture we considered the symptoms, the nature, the causes, and to a certain extent the treatment, of that terrible malady, *tetanus*. There is good reason for believing that it is essentially a disorder of the excito-motory apparatus; that it is caused by irritation of a peculiar kind, affecting that part of the nervous system, and producing tonic spasm of the voluntary muscles; that the irritating cause may be centric, situated within the spinal canal, and applied directly to the cord; or eccentric, situated out of the spinal canal, applied to some part of one or more of its afferent nerves directly, and thus influencing indirectly the cord itself, and through it the reflex motor nerves; and that a certain ill-understood state of the system is necessary, a certain aptitude to take on the disease, before the exciting cause can be efficient; and that one circumstance which has been ascertained to tend to the production of such an aptitude, is a long-continued high temperature of the atmosphere.

I mentioned several remedies and plans of treatment which have been fairly tried, and mostly tried in vain, for the removal of this disease. The severe cases, and especially the severe traumatic cases, almost all prove

fatal; the less severe cases, those in which the paroxysms are less violent and less frequent, and which run on for several days, sometimes terminate in health: whether in consequence of the measures employed, or whether in spite of them, it is not easy to say. The idiopathic cases, as they are called, those which appear to be produced by exposure to cold and wet, are usually the least severe, and the more hopeful. The remedies that have been tried, and which were mentioned originally in its milder form. So that whether the complaint was actually cured in any of these cases, whether, *i. e.* any single patient recovered, or recovered sooner, from using any of these remedies, who would have died, or in whom the disease would have been protracted, if he had *not* used them, is a matter of uncertainty.

The celebrated American physician, Dr. Rush, regarding the disease as essentially a disease of debility, and looking probably at its common tendency to death by asthenia, wrote a paper to recommend the employment of bark, and wine, and spirits, in full doses. It is curious enough, but quite in agreement with what has been already stated of opium, that how much wine soever may be swallowed by the patient, nothing like intoxication is produced by it. The system resists the ordinary influence of the alcohol. In one instance related by Dr. Currie, the disease lasted six weeks, and in that space of time the patient drank 110 bottles of port wine. The same author mentions a remarkable case, in which a horse, which was attacked by tetanus, and happened to be a great favourite with its master, was treated with wine, and got well, after swallowing more port wine than he was worth. Whenever

this plan has appeared to do good, it has been in the more chronic variety of the complaint.

Mercury, you may be sure, has not been left untried. It is said that the system is slow in submitting to its influence, in this malady. The specific effect of mercury upon the gums is not, however, so strongly resisted as that of wine or opium upon the nerves. Nor can we be surprised at this, when we consider that in tetanus the functions of organic life, are, comparatively, but little involved. It is clear that there is not time for any effectual exhibition of mercury in those severe cases that are early fatal. In its more chronic form the disorder has been known to yield upon the mouth becoming affected. This happened, if I mistake not, in Mr. Mayo's patient, mentioned in the last lecture. Tetanus has sometimes, however, commenced while the patient was in a state of salivation. Dr. Wells has recorded three instances of that kind. The experience of the military surgeons who were in Spain is, upon the whole, against the reputed efficacy of mercury. We must take care not to conclude too hastily that because a patient uses a certain remedy and recovers, he recovers through the operation of that remedy: any more than we should conclude, if he recovered during a general election, that the election had cured him. Yet this absurd and unsafe mode of reasoning is for ever employed in respect to disease, by the public: and too often, I fear, by ourselves.

Purgatives have been much given in tetanus; and often with manifest advantage: I mean in the less severe cases. But very large doses are commonly required to produce evacuations from the bowels. Whether the torpor of the intestines be always the effect of the disease, or whether it may not sometimes be, in part at least, the consequence of the opium that is given, I am not sure. When they do act, very unnatural motions are frequently produced: Mr. Abernethy tells us of a hospital patient of his who recovered under the use of purgatives: they were long before they had any effect, and when they did at last operate, such foetid stuff came from him that no one who could crawl out of the ward would remain in it. He says also that the nurses, in other cases, have reported the stools to be more like sloughs than fæces. Enormous quantities of drastic purgatives have been given. You may read an instance of this in the second volume of the *Medico-Chirurgical Transactions*. It is related by Mr. Harkness. There is a still more extraordinary case detailed by Dr. Briggs, in the fifth volume of the *Edinburgh Medical and Surgical Journal*. In little more than 48 hours, the patient in that case took 210 grains of scammony, 89 of gamboge,

80 of calomel, an ounce and four scruples of jalap, and $2\frac{1}{2}$ pints of what we call *black dose*, the infusion and tincture of senna: and all this without either sickness or griping; but on the contrary with the most decided benefit. In the first week of his disease, the patient swallowed—of calomel, 280 grains; scammony, 260; gamboge, 110; jalap, 3 ounces and 10 grains; infusion of senna, $5\frac{1}{8}$ pints. And altogether in the first 25 days—of calomel, 320 grains; scammony, 340; gamboge, 126; jalap, 5 ounces and $7\frac{1}{2}$ drachms; infusion of senna, $10\frac{1}{2}$ pints; besides an ounce and a half and 35 grains of the colocynth pill. I mention all this to shew what the system will bear, under the bondage of the disease; not as an encouragement to you to prescribe such doses.

It is certainly proper and necessary to clear out the bowels, and to endeavour to correct unhealthy secretions; yet numerous evacuations, the act of going to stool often repeated, should be avoided. Under such obstinacy of the bowels, the croton oil would perhaps be the most eligible purgative.

Foxglove and *tobacco* are two medicines, or rather poisons, which have been used; both, probably, upon the same principle. Their effects, when full doses have been given, are much alike: sickness, faintness, feebleness and fluttering of the pulse, coldness of the surface, with that slack and passive state of the muscles which belongs to syncope. But if we consider that the influence of these substances upon the involuntary muscles, especially upon the heart, is more certain and decided than upon the muscles of voluntary motion, which are the muscles involved in the tetanic spasm, and if we take also into account the strong disposition observable in tetanus towards death by asthenia, we shall scarcely be prepared to expect any good, but the contrary, from digitalis, or tobacco: especially in the later periods, when, so far from obviating the tendency to death, they would seem to co-operate with the disease in extinguishing life. However, if the result of experience were clearly in their favour, we should not be warranted, by mere theoretical views, in withholding these drugs. The army surgeons, some of them, have fancied digitalis useful. Sir James McGrigor mentions a case in which it caused a relaxation of the spasms; but the man died afterwards, apparently from the effects of the remedy. And this is just what I find with digitalis. When given in large doses (and small ones here must be useless) it becomes unmanageable. Certainly we have no such accounts of its salutary power as would induce me to give it with much expectation of success, or to give it at all.

The tobacco is not given by the mouth, but thrown up into the rectum: either the smoke of its burning leaves, or (what is probably as efficacious, and I should think more uniform and less unsafe) an infusion of them in water. Mr. Curling, after analysing a large number of cases of tetanus, thinks tobacco the best remedy we at present possess. Mr. Travers is of the same opinion. However, I should recommend great caution in the use of this ticklish remedy. You ought to know that, when injected in other emergencies, in strangulated hernia, for example, mortal syncope has followed such enemata.

Musk, in large doses, has been strongly recommended by a Frenchman, Fournier-Pescay, who has written on this disease. He gave ten or twenty grains, at intervals; so that a drachm, or even two drachms, were taken in the course of the day; and he declares that he found it more efficacious than any thing else that he had tried.

Prussic acid and belladonna are said by Dr. Elliotson to have been freely employed, and to have failed: whether in his own hands, or in those of others, I do not know.

There is another remedy which the same physician has employed; and employed not without success: *the carbonate of iron*. Reflecting, he tells us, upon the good effect of this medicine in another complaint which has some points of analogy with tetanus, viz. chorea, of which I shall soon speak, and considering how miserably narcotics had failed, he determined to give the carbonate of iron a fair trial, upon the first opportunity. He has published some account of its effects, in tetanus, in the *Medico-Chirurgical Transactions*. In the first case in which he used it, the tetanus supervened upon a compound dislocation of the great toe. The method in which the remedy was administered was this: the carbonate was made into an electuary by mixing it with twice its weight of treacle. The electuary thus made was well mixed with beef-tea just as the patient was about to drink it. He took this every two hours, as much as he could swallow: and he got well. The next case is described as being a very severe one; it resulted from a contusion of the thumb. Dr. Elliotson says that he never saw a case, *which did well*, that was more severe. This patient also took the carbonate of iron, as much as could be got down; and that was about two pounds a day. He had injections twice daily, to keep the bowels unloaded: and the iron is described as having come away in large red lumps, in shape like horse-dung. This man recovered. In a third case, where a chilblain above the heel was the exciting cause, the boy died within 24 hours of the time when the remedy was first prescribed. To produce its effects upon the system (Dr. Elliotson observes, very truly)

iron must be given *for a few days*: nay he holds that months sometimes elapse before it has any effect. So that if it really be useful in tetanus, we cannot expect much good from it in the more acute cases: and these are the cases for which we want a remedy.

Oil of turpentine is one of the many substances that have been praised as useful in tetanus. Now bearing in mind its power (which I shall hereafter describe, but which you must at present take for granted) as a worm-killer, and also the frequency with which worms are met with in the stomach and bowels after death by tetanus, this is one of the drugs which I should employ as a *purgative*, taking my chance of whatever good might possibly arise from its specific or anthelmintic qualities. It may be given in such cases either by the mouth, or in an enema, or at both ends together: but it must be given in large doses, not less than an ounce at a time; and it may be mixed with an equal quantity of castor oil. The one oil dissolves or becomes incorporated in the other.

Strychnia has been suggested as a remedy for severe tetanus: not in infinitesimal doses, as Hahnemann would, I suppose, prescribe it, but in sufficient quantity to produce a sensible effect. The principle upon which this has been recommended is the same with that on which the nitrate of silver ointment is applied to the inflamed conjunctiva in purulent ophthalmia. We know that strychnia acts upon the spinal cord, affecting apparently those parts and those functions of the cord which are affected in tetanus: and in so fatal a malady, it would be justifiable, I conceive, to give the strychnia, in the hope that it might occasion a morbid action which would supersede the morbid action of the disease, and yet be less perilous and more manageable than it. But it would be right to try such a remedy as this, in the first instance, *in corpore vili*; upon one of the lower animals. This, were it successful, would be a cure, according to the Hahnemannian doctrine—*similia similibus curantur*—a doctrine much older, however, than Hahnemann. But the opposite maxim, *contraria contrariis*, has been suggested. Mr. Morgan proposes to give such poisons as are known to cause paralysis, with the view of countervailing the undue action of the muscles in tetanus. He produces artificial tetanus by inserting a poison brought from Java, called “*chatic*,” into a wound, and then relieves the tetanic symptoms by a North American poison, the *ticunas*. Professor Sewell, of the Veterinary College, has tried this principle in one case at least, where the tetanus was the result, not of any poison, but of disease. Not having had an opportunity of getting the

particulars of this case from Mr. Sewell himself. I give you Mr. Mayo's account of it. "A horse, suffering from a severe attack of tetanus and locked-jaw, the mouth being too firmly closed to admit the introduction of either food or medicine, was inoculated on the fleshy part of the shoulder with an arrow point coated with the wourali poison. In ten minutes apparent death was produced. Artificial respiration was immediately commenced, and kept up about four hours, when reanimation took place. The animal rose up, apparently perfectly recovered, and eagerly partook of corn and hay. He was unluckily too abundantly supplied with food during the night. The consequence was over-distension of the stomach, of which the animal died the following day, without, however, having the slightest recurrence of tetanic symptoms." I had fancied that the death had resulted from some injurious effect upon the lungs, produced by the artificial breathing. But I have little doubt that Mr. Mayo derived his statement from Mr. Sewell himself. The experiment deserves to be carefully repeated.

I have but little to say concerning what may be called the surgical treatment of traumatic tetanus. It was a natural thing, the source of the irritation being supposed to be the wound, to expect relief from amputation of the limb. But that will not arrest the morbid action after it has once been fairly established. Dr. Elliotson says he has searched scores of books, and found only one case in which the limb and the disease were lopped away together. However, Mr. Blizard Curling, in his *Essay on Tetanus*, refers to seven instances of recovery, after the injured part had been amputated. Yet he states that "it is almost impossible to assert in with certainty how far the amputation, in these cases, was of service." I believe I cannot offer you better advice on this subject than may be gathered from the concluding remarks of a very distinguished and philosophical surgeon, in his lectures on the disease. I allude to the late Mr. Abernethy, whose pupil I had the good fortune to be. He said, "The state of the part injured is not the sole cause of tetanus. In cases of tetanus I have often amputated injured fingers; and though I did not thereby save my patients, yet I think that the symptoms were mitigated after such amputations. In such cases then, I would not amputate any considerable member; nor even a small one, unless I thought that, from the injury sustained, it would prove useless to its possessor, even though the case should terminate favourably."

The tourniquet has been applied to the hurt limb; but not, so far as I know, with any good effect. The most promising expedient which surgery offers is the division of

the principal nerve proceeding to, or rather from, the seat of the injury. This, supposing the nerve to be known, and accessible, is less formidable, less severe, less hazardous, less maiming, and, if we may judge from past experience, more effectual too, than amputation of the part. Dr. Murray has recorded (in the 11th volume of the *MEDICAL GAZETTE*) a very interesting case in which the operation was followed by most decided and instant relief. The patient was a young midshipman, who having trodden on a rusty nail, which pierced the sole of the left foot, had kept watch the same night upon deck, the weather being very cold. The disease began the next day, and the symptoms ran high. It was a case, therefore, of severe or acute tetanus. Without loss of time the posterior tibial nerve was divided. The limb was previously cold, and as the patient said, dead, and he had little power of moving it. He could not articulate distinctly, on account of the closed state of his jaws. The nerve was cut through by one stroke of the scalpel; and "immediately (says Dr. Murray) he opened his mouth with an exclamation; and on looking at his countenance I was astonished at the striking improvement in it. I asked him how he felt, and he said he was already much better, and that his leg had come to life again." Some stiffness of the jaws and neck remained for a day or two; but he soon recovered. Dr. Murray refers to another case mentioned by Baron Larrey, in which division of the nerve had a similar result.

Probably, to be successful, the operation must be *early*; before the morbid condition peculiar to the disorder has had time to root itself in the nervous system.

Although, in the present state of our knowledge, there is no one remedy or plan on which we can rely for the cure of this fearful malady, we may with much confidence lay down certain general rules, the observance of which will secure to the patient the best chance of a favourable result.

Since any the smallest movement, or impression made upon the surface, or upon the senses, will bring on the severer degrees of spasm, it is of primary importance to protect the patient against these sources of trouble, so sure to aggravate his sufferings, and so likely to augment his danger. Hence if blood-letting should be thought advisable, it should be done early, sufficiently, and once for all. There should be no repetition of venesection or of cupping, or of leeches, unless the circumstances and progress of the case plainly demand them. The same remark applies to the frequent use of purgatives. The bowels should be well cleared in the outset, and then let alone. The patient should lie in a darkened room; from which noise also should, as far as may be possible,

excluded. He should not be surrounded by a multitude of friends or attendants. He should be enjoined to speak, to move, to swallow, as seldom as he can. In the severe traumatic cases, the nerve (in my judgment) should be promptly divided. And in all cases, there being no special indications to the contrary, I should be more inclined to administer wine and support, in large doses, than any particular drug. If the tendency to mortal asthenia can be staved off, the disturbance of the excito-motory apparatus may, perchance, subside or pass away.

There is a form of this complaint called *trismus nascentium*. As the name implies, it occurs in newly-born children. It is very frequent, and very fatal, in the West Indies: coming on usually in the second week after birth. Hence it has been called, "the ninth-day disease." Another of its names in the British settlements there, is the "jaw-fall;" from the circumstance that shortly before death the lower jaw, which had previously been firmly pressed against the upper, drops on the breast. It has been said that a fourth of the infant negroes in Jamaica used to die of this disorder. Some persons refer it to the irritation produced by the retention of the meconium in the intestines: others to irritation from the wound made by dividing the navel-string. A dose of purgative medicine appears to be the most hopeful remedy.

Tetanic symptoms sometimes occur (but I should think very rarely) in ague. Or paroxysms of tetanus return at regular intervals, and terminate by profuse perspiration; the patient being well during the intermission. When such phenomena arise, the treatment proper in severe forms of ague must be adopted: what that treatment is, I shall, in no long time, be able, I hope, to lay before you.

Again, tetanus is occasionally a symptom in hysteria: and then the treatment applicable to hysteria must be had recourse to; especially enemata of oil of turpentine, or the same medicine given by the mouth; and the cold affusion.

If the disease of which I have been speaking be dangerous, and very often fatal, in spite of all remedial measures, that which I propose to bring next under your attention is still more appalling; for I believe that, hitherto, it has been uniformly mortal. I know not that any one has ever been rescued by art, or saved by the efforts of nature, from *Hydrophobia*, after that frightful disease has once declared itself by its characteristic symptoms. The nature of these symptoms, and the absence of all constant or satisfactory traces of organic change in the dead body, sufficiently mark the disease as belonging essentially to the nervous

system, and as being essentially a *spasmodic* disease also.

What are the symptoms, stated in broad outline? These. Excessive nervous irritability and apprehension; spasmodic contractions of the muscles of the fauces, excited by various external influences, and especially by the sight or sound of liquids, and by attempts to swallow them; and extreme difficulty, amounting sometimes to impossibility, of drinking.

This is one of the diseases which are produced by animal poisons; and its course will be most conveniently traced if we include in our description of it the very first step towards the complaint—the application of the specific poison to the body. A man is bitten by a dog. After a time the symptoms proper to hydrophobia come on. After another interval the man is dead. Before we advert to the many very interesting points of enquiry which arise out of the contemplation of this malady, let us follow the tragedy from its commencement to its closing scene.

A person is bitten, then, by a mad dog. Does the existence of rabies in the animal modify in any way the injury thus inflicted? No: the wound that is made behaves just the same, to all appearance, as it would have behaved if the dog had not been rabid; and it gradually heals. After an uncertain interval—which lies, *for the most part*, between six weeks and eighteen months, and which has been called the period of *incubation*—these symptoms begin to be noticeable. The patient experiences pain; or some uneasy or unnatural sensation, in the situation of the bite. If it has healed up, the cicatrix tingles, or aches, or feels cold, or stiff, or numb: sometimes it becomes visibly red, swelled, or livid: on one occasion a papular eruption took place around it; sometimes it opens afresh, and discharges a peculiar ichor. The pain or uneasiness extends from the sore or scar towards the central parts of the body: *i. e.* if the bite has been inflicted on a limb, the morbid sensations extend towards the trunk. All this gives fearful notice of what is about to happen. This period is called the period of recrudescence. I believe it seldom fails to occur, although it sometimes is not noticed: the attention of the patient, and of his medical advisers, being absorbed by the horrible sequel. Very soon after this renewal of local irritation—within a few hours perhaps, but certainly within a very few days, during which the patient feels uncomfortable and ill—the specific constitutional symptoms begin: he is hurried and irritable; speaks of pain and stiffness, perhaps, about his neck and throat; unexpectedly he finds himself unable to swallow fluids, and every attempt to do so brings on a paroxysm of

choaking and sobbing, of a very distressful kind to behold; and this continues for two or three days, till the patient dies exhausted; in the way of asthenia.

I have seen only two examples of this terrific malady: one in St. Bartholomew's Hospital, in the year 1826; one much more recently in the Middlesex Hospital. As they constitute the whole of my personal experience in the matter, I shall relate these cases.

The first occurred in a coachman, the back of whose right hand had been struck, ten weeks previously, by the teeth of a terrier dog: but, as both the patient and his fellow servants declared, there was no wound made, no blood drawn, no breach or liting of the skin; but merely an indentation, shewing where the animal's teeth had pressed. He was brought to the hospital on a Tuesday. On the preceding Thursday his hand had become painful, and swelled a little. On Friday the pain extended into the arm, and became more severe. His wife stated that he had been in the habit of sponging his head and body every morning with cold water, but that, on this morning, he refrained from doing so, on account of some feeling of spasm about the throat. His own remark on this was, that "he could not think how he could be so silly."

On Saturday the extent and the severity of the pain had still farther increased. On this and the preceding night he got no sleep. He felt ill and drowsy on the Sunday, but drove the carriage to Kensington Gardens: he was, however, obliged to hold both whip and reins in his left hand. The pain extended to the shoulder. He was then bled. A slop-basin full of blood was taken, with much relief to the pain; and purgative medicine was given, which operated well.

The next day he complained of "feeling very ill all over," and he told his medical attendant that he could not take his draughts, because of the spasm in his throat. That gentleman (Mr. Macdonald), concealing his own suspicions as to the true nature of the disease, said, "Oh, you don't like the taste of your physic! drink some water." But he declared he had the same difficulty with water. The next day he came to the hospital. When there, water was brought and placed before him in a basin, for the alleged purpose of allowing him to wash his hands. It did not seem to disturb him, nor to excite any particular attention. Water was then offered him to drink, which he took, and carried to his mouth, but drew his head from it with a convulsive shudder. After this, on the same morning, he was much questioned by several persons about the supposed cause of his illness; and water was again brought him, which agitated him, and he became exceedingly distressed and unquiet, complaining of the air which blew upon him.

I first saw him myself soon after this. He was then, to all outward appearance, well; lying on his back, without spasm, without anxiety; his face was somewhat flushed. He said he had a little headache, but no pain in the arm. His pulse was 132, full, and strong; his tongue moist, and slightly furred. He appeared to be a very quiet good-tempered man; and smiled generally when he was spoken to.

I was naturally much interested by this case, and at nine in the evening I visited the patient again. He was composed and quiet. Gruel was mentioned, and then he sighed two or three times deeply; then sat up, and, after a moment's look of serious terror, took half a spoonful of the gruel in a hurried gasping manner; and said he would not take more at a time, lest the *sensation* should come on. He was desired to drink the last portion of the gruel from the basin. He accordingly seized it with hurry, carried it to his mouth with an air of determination, and then a violent choking spasm of the muscles about the throat ensued, the sternocleidomastoidei starting strongly forwards. Most of the gruel was spilled over his chin; and he observed that he had been too much in a hurry, or he should have managed it.

The treatment consisted in full doses of opium, repeated at frequent intervals. On this visit to him I noticed that while attempting to take some of the gruel with a spoon, he seemed inclined to doze as he sat. Otherwise there were no signs of his being overwhelmed, or even sensibly affected by the opium; except that his general quietness might have been the consequence of it. He was quite calm and rational, except when attempting to take fluids.

On the Wednesday, at noon, he was nearly in the same state, but said he was better. In the course of the night some bits of ice had been given him: with considerable effort he swallowed two or three of these; the third or fourth caused so much spasm, however, that he was obliged to throw it out of his mouth: but so great was his resolution that he seized it again, and, by a strong exertion, succeeded in swallowing it. He complained now that his mouth was and had been clammy; and he champed much, and spat out a good deal of tough mucus. At his own request, and (as he said) that he might injure no one, a straight-waistcoat was brought, which he assisted in putting on. But he was perfectly calm then.

I now had an opportunity of seeing him take some arrow-root. He sat up in bed to eat it; and before attempting to do so, he made hurried inspirations, and sobbings precisely resembling those which occur when one wades gradually into cold water. He took small quantities of arrow-root eight or nine times, with hurry and difficulty, and

with sighs that succeeded each other rapidly. He said that he felt the upper part of his throat narrower than it should be. He continued to take laudanum mixed with sugar and bread into a kind of pulp.

By the evening of that day the disease had not made much farther progress. He again sat up and tried to take some thinnish gruel. While taking the basin into his hand, he drew back his head to a distance from it, apparently involuntarily. He took one half-spoonful with effort and difficulty, then sighed deeply and rapidly, or rather his breathing consisted of a succession of sighs at short intervals: he gave up the basin, and sank back on his pillow still sighing. In the course of that night he ceased to take the laudanum; he could no longer attempt it. The next day he was still composed, though more easily irritated; and it was found that he had lost the power of moving the left arm. His pulse was 140, and much weaker than before, and his mental powers were failing. He gradually sank, and died in the evening, having repeated the Lord's Prayer an hour previously. During the last hours of life he had been moaning, and tossing from side to side: his bowels were purged; fluid stools ran from him, and distressed him greatly. His lower extremities first became cold, and the coldness extended by degrees up to his chest. He hawked up in the course of the day a considerable quantity of ropy mucus, and much frothy saliva came from his mouth towards the close. As his wife was wiping this away, whether by convulsive accident or otherwise, his teeth came in contact with her finger, and drew blood. The part was cut out; and no bad consequence followed that I know of.

The examination of the body threw no satisfactory light upon the essential nature of the disease. Blood and serous fluid escaped on the removal of the calvarium. The vessels of the membranes were full, and the brain itself was mottled somewhat by its vascularity. There were a few spots of ecchymosis on the heart. The back part of the tongue was very vascular. The stomach presented the most notable appearance. There was a quantity of brownish-coloured mucus on its inner surface, and the mucous membrane had disappeared from a space about four inches in diameter at its larger extremity. That space alone was diaphanous; its edges sloped inwards; and a segment of this thin place looked exactly like a piece of china: on a white ground, there were inosculating vessels, some of them blue, and some of them of a coffee-coloured brown. I conclude that this appearance was produced by the action of the gastric juice after death.

This was in some respects a remarkable case. It was remarkable for its duration. Dr. Bardsley, in the article on Hydrophobia

in the *Cyclopædia of Practical Medicine*, states that the patients "invariably go on from bad to worse, and finally die before the sixth day." Now if we reckon that stage of the complaint here referred to by Dr. Barlow to have begun on the morning of Friday, when he was obliged to omit his sponging because of the spasm about his throat, this patient did not die till the middle of the seventh day. In fact it was a very protracted case: and the symptoms were less violent than usual: whether this was owing to the opium he took or not, it would be difficult to determine.

In the second of the two cases which it has been my lot to witness, the characteristic symptoms of hydrophobia were more faintly pronounced than is usual.

On going to the Middlesex Hospital, on Thursday, the 5th of October, 1837, I was told that a patient had been admitted (under one of my colleagues) labouring probably under hydrophobia. He had applied at the hospital in the middle of the night; but was then sent away, after receiving some aperient pills, with assurances that he was only feverish and nervous. On his reapplication in the morning he had been admitted.

I found him in the ward: a man twenty-five years old, of dark complexion and hair. He expressed his conviction that he was afflicted with hydrophobia; and said he was prepared for his fate. I observed that every now and then he suddenly sighed in a very peculiar manner: just as I had seen the former patient sigh. This would happen sometimes in the middle of a sentence, while he was speaking. He told us he had been bitten by a dog in the latter end of July; the dog was swimming, and like to drown, in a canal, and upon his reaching over to lift him out of the water, the animal seized upon his hand. After dragging the dog out, he beat him for his ingratitude; and then the dog ran off, and was pursued by a mob of boys, who had previously been pelting him as a mad-dog. There was a scar on the middle finger of the right hand; the nail of that finger had (he said) been torn through, and each of the two adjacent fingers had been more slightly bitten. His pulse was 84; but varied in frequency at short intervals.

He acknowledged that after receiving the bite he was uneasy as to its possible effects, and read books about hydrophobia at the time: but he affirmed that he had afterwards ceased entirely to think about it. He had persuaded himself that the dog could not be mad, from its being in the water. On Tuesday, if not earlier, he had been uncomfortable and restless; and on Wednesday he found he could not swallow liquids. On one of these days he experienced a slight pricking sensation, without any redness or tenderness, in the site of the scar; his right arm and leg seemed to himself lotter than the opposite

limbs; and the arm, though not tender, felt raw, and he could not bear the light contact of his clothes upon it. He became feverish also. From time to time a slight expression of terror passed across his features, and then he made a sudden, deep, sighing, inspiration: at other times his breathing and appearance were perfectly natural. It was said that when some water was brought him he drew himself back from it with horror. He talked a good deal.

I saw him eat rice, made pulpy with milk. He took it without looking at the spoon, from which he averted his eyes, and ate several mouthfuls, in a gulping manner, and with evident effort. His bowels had been purged by the pills, and he declared that the noise of the water in the water-closet had distressed him. The sound of some water poured from one vessel into another by the patient in the next bed, had also agitated him. So did the contact of my cold hand on his arm; and currents of air, even the breath of any one speaking to him; so that he insisted on conversing with the apothecary in such a position that the chin of each was on the other's shoulder. But there was no actual or apparent spasm.

At this time he affirmed that the presence of company cheered him, and did him good; and begged that he might not be removed into a separate room. And he wished for some amusing book that he might read.

In the evening I again went to see him. He did not seem worse, though he said "his symptoms were increasing." He had taken a dose of musk, and some morphia.

The next day I found the hospital in some confusion. Between eleven and twelve o'clock in the preceding night some of the officers of the hospital had gone to his bed, while he was apparently asleep, and certainly very quiet. They asked him if he would like some water. This seems to have greatly excited him; and immediately after their departure he rushed out of bed, (terrified, he said,) became furious and unmanageable, and was never again quiet till he died, about the same time the next night. He was now put into a room by himself; and, taking advantage of the momentary absence of the nurse, he bolted himself in alone; and declared he would admit no person but her. The door was at length forced, and a straight-waistcoat was put on him. He then became quieter in his manner; begged that no unnecessary violence might be used; asked to be poisoned; spat at some of the bystanders, and reproached them, talking rapidly and wildly like an insane person; yet loudly and angrily imposing silence on every one who addressed him. He said he could not bear to hear any one speak; that he did not like my bass voice. Then he would sneer at the students, and say they showed bravery

enough now he was confined: "was it right for young gentlemen of education to stand there gazing with curiosity on a dying man?" asked for bread soaked in water, and when it was held towards him, snatched it in his mouth in a savage manner; spoke of his "poisoned tooth," and talked perpetually. He took a fancy to one of the students, and begged that he might remain with him.

About this time he vomited some yellow fluid, and thought he felt the better for it, and asked for an emetic; and some tartarized antimony was exhibited. He was now pale, and his lips were livid; but none of the distinctive spasmodic attacks occurred: indeed water was not at this time suffered to be brought near him. This circumstance it was, this absence of the peculiar spasmodic paroxysms which characterize hydrophobia, that induced several medical men of much sagacity and experience to doubt, and even with some positiveness to deny, that the patient was suffering under that disease at all. They supposed him to be hysterical, half-crazy, or on the brink of delirium tremens. But though slightly expressed, the symptoms were unlike any thing I had ever seen, except in the previous instance. And the closing scene was quite distinctive.

It appeared, and he spoke of it as a thing which distressed him, that when he was most excited, his urine passed involuntarily.

In the evening I found his father with him. He had recognized him, and kissed his mother-in-law; but soon began again to rave, and to be apparently occupied with absent persons. He was pale and weak, and lay with his head over the bed, spitting continually upon the floor, which was thus made quite wet. He wished to have his hands at liberty that he might "clear his mouth." He was soliloquizing when I went into the room, in this way. "Monsters—monsters—see that monster Susan—take her away." (It appeared that he was now speaking of a young woman who had had a child by him.) "I thought they would do much for science, but never supposed they would inflict such agony as this;" and so on.

A little later Mr. Arnott visited him. He had then no pulse at the wrist. The waistcoat was removed. He sat up, and used some water, brought to wash his hands, without apparent distress. Soon after he sunk back exhausted; and expired.

His father corroborated what the patient had said of the dog: and told us his son was clever, and better educated than many of his rank (he was a tailor), and always exceedingly nervous.

The body was examined the next day. Its posterior and undermost surface was very livid. The blood every where quite fluid. The veins of the spinal cord, on its posterior part, were turgid; not at all so on the anterior. The substance of the cord was

quite natural. There was some fluid in the theca. The brain appeared to me, in every part, quite sound and healthy.

The head and face, which had been hanging over the table while the spinal canal was opened from behind, were deeply purple, as though universally bruised. This colour diminished rapidly after the corpse was placed supine, and the head raised somewhat above the level of the body. The papillæ at the back part of the tongue were greatly exaggerated, and looked like large vesicles. The cartilage of the epiglottis, at its lower part, was red. At about the middle portion of the œsophagus there was an appearance as if the cuticle was abraded. The mucous membrane of the stomach was soft, and red here and there, with a dotted injection resembling ecchymosis, especially on its rugæ. The air-passages were apparently healthy.

Generally, the disease, when it has once set in, and shown the peculiar hydrophobic symptoms, runs a short and fierce course. The nervous irritability becomes extreme; the peculiar paroxysms of choking spasm, and sobbing, are excited, not only by attempts to swallow liquids, but by the very sight or sound of them; Dr. Elliotson mentions a boy who was thrown into a state of violent agitation by hearing a dresser who sat up with him make water: the passage of a gust of wind across his face, the waving of a polished surface, as of a mirror, before his eyes, the crawling of an insect over his skin, is often sufficient to excite great irritation, and the peculiar strangling sensation about the fauces, in a hydrophobic patient. These circumstances were but little observable in the men whose cases I have related; the first of them indeed was remarkably calm and tranquil under the disease. In general the patient is dreadfully irritable, and apprehensive and suspicious: and in most cases there is a degree of mania or delirium mixed up with the irritability; the sufferer is very garrulous and excited. In this respect there is a marked difference between hydrophobia and tetanus. In the latter disorder the mental faculties are clear, and the patients serene, and what is called heartwhole, to the last. The two diseases differ in another striking particular: the spasm in the one case is tonic, in the other clonic. In tetanus, again, there is no thirst, and seldom any accumulation of tough and stringy mucus in the fauces and about the angles of the mouth: in hydrophobia both these symptoms are almost always present. So also is vomiting; but vomiting in tetanus is rare. The nervous irritability in hydrophobia is doubtless a part of the disease, and is very rarely absent even now-a-days. Some time ago it might perhaps have been plausibly attributed to the treatment adopted. I allude to that period in which it was believed that these miserable

persons had both the power, and the inclination, to impart the disease to others by biting them; and when, under pretence of shortening *his* sufferings, but really, I am afraid, with the cowardly view of protecting *themselves*, his friends were accustomed to smother the unhappy patient between two feather beds, or to open a vein, and to leave him to bleed to death. Any person, suspecting what was the matter, and foreseeing such a termination to his disease, might well be nervous and irritable. But now that this barbarous practice has been exploded, and the dread of being smothered does not occur to the mind of the patient, he is still found to be exquisitely irritable and timorous. The foam and sticky mucus that gather in the throat and mouth, these patients make great efforts, by spitting and blowing, to get rid of; and the sounds they thus produce have been exaggerated, by ignorance and credulity, into the barking and foaming of a dog. In the same way the paraplegia which sometimes takes place, rendering the patient unable to stand upright, has been misconstrued into a desire on his part to go on all fours like a dog. The pulse, though it may be strong and hard at the outset, becomes, in a short time, frequent and feeble, and the general strength declines with great rapidity. Death occasionally takes place within twenty-four hours after the commencement of the specific symptoms. Most commonly of all it happens on the second or third day; now and then it is postponed to the fifth day; and in still rarer instances, of which my first case was one, death does not occur till the seventh, or eighth, or ninth day. In most cases, the paroxysms, becoming more violent and frequent, exhaust the patient; but in a few instances the symptoms undergo a marked alteration before death. The paroxysms cease, the nervous irritability disappears, the patient is able to eat and drink, and converse with ease; those sights and sounds which so annoyed and distressed him before, no longer cause him any disquiet. In this state he often sinks into a sleep, and suddenly wakes from it to die: sometimes his existence is put an end to by a sudden and violent convulsion.

It is needless for me to go into a minute account of the morbid appearances that have been met with in persons dead of hydrophobia. They are various, uncertain, unsatisfactory. In some bodies, the most careful examination has discovered nothing amiss. In others, vascularity of the brain, or of the spinal cord, has been noticed. And in not a few instances the mucous membrane of the fauces, œsophagus, and stomach—or of the larynx and trachea—or of both these tracts—has been found red, and covered with adhesive mucus. But we must take care not to attribute undue importance to these last appearances—not

to conclude that they have been the cause of the symptoms, when in truth they may have been the effect of the disease. That we should find the parts in the throat red and congested is what we might naturally expect, when we consider the violent straining spasmodic action of these parts for some time before death. The morbid anatomy of this disease throws but little light upon its nature, or its proper treatment.

There are many very interesting questions connected with hydrophobia. I will state the principal of these, as shortly as I can.

1. You will be surprised when I tell you that some persons have made it a question whether there is any such disease at all. I have known such. The late Sir Isaac Pennington, who was Regius Professor of Physic at Cambridge, had never seen a case of hydrophobia, and nothing could persuade him that any one else had seen any thing more than a nervous complaint produced by the alarmed imagination of the patient, who having been bitten by a dog reputed to be mad, and having the fear of feather-beds before his eyes, was frightened into a belief that he had hydrophobia, and ultimately scared out of his very existence. Now if you meet with such incredulous persons, and think it worth your while to argue the point with them, you may object to their unbelief, the improbability that so many persons who have been bitten by mad dogs should have suffered so precisely the same train of symptoms, and at last have died, from the mere force of a morbid imagination; you may urge them with the fact that many of these persons have been under no apprehension at all, until the disease has seized upon them; that many also have been men of naturally strong and firm minds, not at all likely to be frightened into believing that they were seriously ill unless they really were so, and still less likely to be terrified into their graves. And if this has no weight with such reasoners, you may bring forward the conclusive facts that the disease has befallen infants and idiots, who had never heard or understood a word about mad dogs or hydrophobia, and in whom the imagination could have had no power in calling forth the complaint. And if they are proof against this, you must give them up: I can suggest nothing more.

2. Allowing that the disease exists as a real, and not a merely imaginary disease, and also that it is caused by the bite of a rabid animal: this important question arises—has it any other cause?

Setting aside that quibbling application of the term hydrophobia which some writers have chosen to make, to diseases in which, from some painful affection of the throat, the patients have been unwilling to attempt to swallow fluids, there are cases recorded, exactly resembling hydrophobia in their symptoms, and occurring in persons who

were never known to have been bitten by, or even to have been in the presence of, a rabid animal. The celebrated and accurate Pinel has given the history of such a case. There is another by Savitrotte, in the *Journal des Savans* (August 1757). Now it is just possible that this disease may sometimes develop itself in the human body without any contagion having been applied: and it is also possible, and much more probable, in my judgment, that the poison may have been applied without the person's being aware of it. We shall see, by and by, some very possible ways in which that might happen. All that we need concern ourselves with practically, is this—that in 999 cases out of 1000 the disease in the human body is derived from a rabid animal. If it ever be spontaneous, we cannot reckon upon meeting with such a case: indeed, many men pass through life without witnessing the disorder at all.

3. Granting, then, that the disease, in man, is the result of an animal poison, the next question is, from what animals may he receive the infection?

We are sure that the disease, by the inoculation of which hydrophobia may be produced in man, is common in the *dog*, and that it has been communicated to the human animal by the fox also, the wolf, the jackal, and the cat. Mr. Youatt says that the saliva of the badger, the horse, the human being, have undoubtedly produced rabies, and some affirm that it has been propagated even by the hen and the duck. The same author mentions a case in which a groom became affected with hydrophobia from a scratch which he received from a horse that was labouring under the disease. All animals, even fowls, are susceptible of the disease when bitten by the rabid dog. Of course it is an important question to have resolved, whether the saliva of all these is capable of conveying the malady. The case just now mentioned on Mr. Youatt's authority would seem to settle the question as respects the horse: but as horses, cows, turkeys, &c. do not generally bite, we have not many opportunities of supplying a positive answer to the general question: there can be no doubt about the *cat*, the *fox*, the *wolf*, and the *jackal*.

The late Duke of Richmond died, abroad, of hydrophobia, contracted from a tame fox, which was rabid. In the 13th volume of the *Medico-Chirurgical Transactions*, an account is given, by Mr. Hewitt, of several cases of fatal hydrophobia from the bite of a wild and rabid jackal. Many examples are on record of the production of the disease by the bites of mad cats and wolves.

The first case which I have spoken of, as having been seen by myself, would seem to prove, if all the facts were correctly stated at the time, that the saliva of the dog may be sufficient to produce the disease, when it

is merely applied to the unbroken skin. It was affirmed by various persons that the teeth of the terrier did not break the cuticle. But we must take care not to draw a hasty general inference from a single case. Mr. Youatt, who has seen more of the disease probably both in man and in other animals than any person alive, does not think that the saliva of a rabid animal can communicate the disorder through the unbroken cuticle: he believes that there must be some abrasion or breach of surface. He holds, however, that it may be communicated by mere contact with the mucous membranes.

Of its harmlessness on the sound integument he offers this presumption—that his own hands have many times, with perfect impunity, been covered with the saliva of the mad dog. He mentions some singular instances in which the disease has been transmitted by contact of the saliva with the mucous membranes. “A man endeavoured to untie with his teeth a knot that had been firmly drawn in a cord. Eight weeks afterwards he perished, undeniably rabid. It was then recollected that with this cord a mad dog had been confined. A woman was attacked by a rabid dog, and escaped with the laceration of her gown. In the act of mending it, she thoughtlessly pressed down the seam with her teeth. She died.” If these cases be authentic, they are conclusive of this question; unless indeed the lips of those who perished happened to have been chopped or abraded. But Mr. Youatt's own opinion is that the virus cannot be received on a mucous surface without imminent danger.

The disease is said to have been caused by the *scratch* of a cat. But as we know that cats as well as dogs frequently apply their paws to their mouths, especially when the latter part is uneasy, (as it clearly is in mad dogs), this fact, of the production of the disease by a scratch, if thoroughly made out, would not *prove* that the disease can be introduced into the system in any other way than by means of the slaver.

CLINICAL LECTURES,

By DR. CORRIGAN,

*Delivered at the Hardwicke Fever Hospital,
Dublin,*

During the Session, 1840-41.

LECTURE VI.—FEVER, No. 4.

Mode of surveying a Case of Fever. Cerebral Function, lesion of. Want of sleep, and its Effects. Treatment by local depletion. Observations on cold and opium.

IF, as we stand at the bedside of a patient ill of our present epidemic fever, we keep

the definition in mind laid down in one of our previous lectures, viz. that the case before us consists of a disturbance of a number of the vital functions, we take, I believe, the best practical view for treatment. If the pathological analysis we have made of fever be correct, this must be our view; and in accordance with it, when we come to the bedside, let us just look down upon the stricken being beneath us as one whose existence depends upon the continuous performance of those functions, and the danger to whom is just in proportion to the amount of derangement in any one function, or to the sum total of derangement in all. Let us, in short, look upon the existence or life before us, as compounded of several functions, and then examine in detail the derangement of each, or estimate the total amount of derangement in all. The functions which are the most important for us to consider in thus regarding a case of fever, are the cerebral and cerebro-spinal, the respiratory, the circulating, and the functions of nutrition and secretion; the latter including the functions of the intestines, kidneys, skin, &c. Let us just look, for practical treatment, at the individual existence before us as consisting, as it were, of those functions, in successive order for examination. By doing this we not only, I think, get the best practical view of the case, but we also acquire a steady and orderly method of examining the case as to its symptoms, and a rapid power of detecting the lesion of the particular function from which the principal danger is to be apprehended. If we still keep this mode of viewing a case of fever before us, we can understand some parts of practice that may seem, at first sight, to be a strange mingling of treatment; for instance the exhibition of wine, and the application of leeches, both going on at the same time in the same patient. But the analysis we have made will enable us to understand this; the leeching is for the derangement of one function, the wine for the debility of another: we should, however, anticipate, were we to take this point up at present.

Let us now, keeping this analysis still before us, go into the explanation of the treatment we are at present adopting, and the first function we shall consider is the cerebral function. The immense importance of the healthy state of the function of the brain and spinal cord needs not to be dwelt upon. The derangement of the function of the brain seemed to some writers, as Clutterbuck, of so great importance as to constitute the very pathology of fever, and although we do not retain such an opinion, we consider the derangement of the cerebral function as one of the most alarming we have to contend with. There are two very opposite states in which we meet this function in

fever: the first, where its disturbance consists in an aberration from its natural state, marked by a total want of that natural rest which this function requires, so that a patient is for several successive nights without rest. In every case, without a single exception, when this occurs, there follows delirium or derangement of the cerebral function, so that we have at first want of the natural rest of the function, and then invariably the result of that increased excitement of it, or delirium, and then we have what appears to have been the effect of the loss of the natural rest of the function—delirium reacting to increase the very cause that gave rise to it. We had a very good example of the progress of derangement of this function, from loss of its necessary rest or sleep up to the most violent delirium, in the case of Murphy, the policeman, who was in No. 1. He laboured when he came in, for some days and nights, under total want of rest. He then began to rave, and at last furious delirium set in. The cerebral functions are too high in importance in man to suffer derangement long, without that derangement involving danger to life, and the cerebral function cannot continue without serious disturbance, if deprived of its natural rest for many days. Hence it is that we regard with such alarm the want of sleep in the commencement of fever; that we dread such ultimate danger when this symptom exists. The order is, want of sleep, delirium, and last, if unchecked, nervous exhaustion and death. Keeping our attention now in the first place on this function, our first inquiry is as to its state, and our best information as to the amount of its derangement is derived from the answer given to our query as to whether the patient has slept. If the patient has passed a second night without sleep, we have allowed the derangement of this function to proceed as far as we dare, without directing our measures to rectify it. After having the head shaved, wait for no other symptom of derangement of the cerebral function than the want of rest. Apply some leeches to the forehead; the number may be few; we seldom use more than four or six. The result is almost always gratifying: in some cases there is good sleep at once procured, in others only a snatch the first night; the repetition of the leeches is again made the next day, and there is again rest: it is seldom necessary to repeat them more than the third time. There are so many instances in the wards, of almost daily occurrence, illustrating the effect of this treatment on the derangement of the cerebral function, that it is not necessary to point out any in particular. Let us now pause here to ask when we are to use the local depletion, how often, &c.

Suppose we see a patient on the third or fourth day of fever, without any thing very remarkable about the head or face, as to flushing, and with a pulse not only not stronger, but often, as in our fever at present, weaker than natural, are we to use the local depletion? I am sure we ought. There are few points of practice on which I would venture to be so positive, as to our treatment of fever, as the absolute necessity of local depletion to remedy that derangement of cerebral function, want of its proper rest or sleep, which, if allowed to continue, must end in delirium, probably in death. I know of nothing that should prevent us from employing this local depletion, except such an extreme state of depression of the vascular system as does not very frequently exist at the early period of fever, when want of rest is a prominent symptom. The propriety and good effect of local depletion in such cases are strengthened by what we see occasionally take place where epistaxis occurs. The effect of this natural depletion is almost always beneficial. Even where the state of pulse is such as to make us dread the application of but a few leeches, the cerebral irritation rapidly subsides on the epistaxis occurring. A case in which epistaxis occurs may be debilitated by it to an alarming degree, so as to require wine to a large amount, but still the cerebral irritation subsides, the patient sleeps, and the danger of death, if it occur in such a case, is from another cause than the derangement of the cerebral function.

Our present maculated fever has a remarkable tendency to assume a remittent form. We see it in the crisis even when taking place by urine, the urine alternating for many days; portions marking the crisis depositing the lithates alternating with portions containing the floating cloud, so characteristic of the fever being still present. The same character is seen in the affections of the cerebral function, the patient remaining free from headache, and the pain of head returning every evening, or twice a day, for many days in succession. When this occurs, the patient is relieved by the application of two or at most four leeches; and provided we succeed in obtaining rest and alleviation of the pain by this means, and we most often do, we have nothing further to do with the cerebral function: mere heat of head need not be interfered with. There is a practice in high inflammatory fever which is very judicious—the application of ice caps to the head. It is not necessary in our maculated fever as at present existing. I think I may go farther, and say it is not only not necessary, but it is injurious. The character of the fever is not such as to make the circulating function any where carry on its action

well under the depressing influence of severe cold. You may perhaps naturally, at first thought, suppose that local depletion from the head, and ice caps, may act in the same way, and that where one is proper so must be the other. A little reflection will, I think, convince us that they are not so much alike as you may at first sight suppose. In local congestions, for instance, some forms of phlegmonoid erysipelas, as well as other local affections, we use local depletion by incision or by leeches; but instead of following this up by the benumbing effect of cold, we endeavour by heat to give action to the overloaded and enfeebled vessels, while we relieve them by the local depletion. So, in the instance before us, we may relieve the local congestion, which is probably the state of vessels in the brain in our present fever; but it does not follow that because we do this we should keep those vessels under the benumbing effects of continued cold at or below the freezing point. I have seen long-continued application of intense cold to the head in our maculated fever produce slough of the integuments of the forehead and temples. Some of our very worst forms of cerebral disturbance, too, or derangement, are in cases where the scalp is not at all hotter than natural; and we may, I think, aggravate this bad form, by an abuse of the remedy which, in some cases of high febrile action and great vascular energy, is one of our best aids. I have said that the state of the vessels of the brain is probably a state of congestion or passive hyperæmia, to which moderate local depletion is useful, although long-continued cold would be injurious. Analogy may be fairly, I think, brought to bear on this. We find, in nearly all our cases of maculated fever, the capillary vessels passing into a state of passive congestion or hyperæmia. We have positive evidence of this taking place in the lungs by the local signs; there is crepitating rattle resulting from the effusion into the air-tubes. That it is not an active state of inflammation or pneumonia, we have abundant proofs, which we shall come to in another lecture. For the present it is sufficient to say, that this state of vessels in the lungs sufficiently shews its nature by getting well under wine. And if we find the capillaries in this state in the lungs, where we have satisfactory evidence of their state, I do not think it is stretching analogy too far to suppose them in the same state in the brain. In fever the function of circulation shews a tendency to the same derangement through the whole system, and the same functional derangement that is seen in the depending surfaces of the body during the last periods of sinking in fever is seen after death in the hypostatic congestion of

the lungs and internal organs. The case of Toner, who has been very ill for the last few days, but is at present recovering, is instructive on this point. The maculæ are of a deep livid hue, his extremities and lips of a purple colour, and the conjunctiva is of a deep dark red; his pulse excessively feeble and tremulous. There is no local disease, no local cause in the extremities to account for this state of them, apart from the enfeebled state of the function of circulation generally. When we see the circulation in this state, where we have it directly under our observation, we have a right, I think, to believe that such too is more or less its state in internal organs. Thus, if we can in fever get in any organ satisfactory evidence of the state of the function of circulation, we shall scarcely err in assuming the same state to exist in an internal organ from which the signs might otherwise be doubtful.

We have only used opium twice within several months to obtain rest: one was in the case of a female who suffered under great irritation of the mucous membrane of the bowels: there was diarrhœa, gargouillement over the cæcum, very rapid pulse, and delirium, from which she was easily recalled, but into which she as quickly relapsed. A full dose of black drop gave her sleep, and stopped the delirium. The second was the case of a man named Toole, admitted on the fifth and sixth day of fever, but not maculated. He was delirious: his eyes were somewhat suffused, but the pupils were dilated; his tongue was white and moist; his skin was warm, but it did not give that pungent sensation to the hand laid on it that is often felt from a skin in maculated fever, even when not so warm as the skin in this case. His delirium was of very high excitement. He sung loudly, and was very noisy. He got 15 drops of black drop, and slept after it: this occurred on the 10th of Jan., and he left the hospital well on the 23d. A comparison of the local cerebral derangement with the general symptoms led us to the employment of opium in this case. Were the local derangement dependent on inflammatory action, there would be more accordance with this state in the symptoms derived from the tongue, skin, and pulse; but while there was so much local cerebral excitement, without any accompanying correspondent severity, the conclusion arrived at was, that the local cerebral derangement was mere irritation, and the practice adopted after a little deliberation was the exhibition of an opiate. There was immediate sleep, and the fever then went on through the remainder of its progress without any urgent symptom.

USE OF SPLINTS IN CHOREA.

To the Editor of the Medical Gazette.

SIR,

I BEG to forward you some remarks on the treatment of chorea, and shall be obliged if you will give them a place in your excellent journal.—I am, sir,

Your obedient servant,

GEORGE SOUTHAM,
M.R.C.S.L.

7, Crescent, Salford, Manchester,
March 31st, 1841.

There are few diseases more obstinate and tedious to cure than chorea, and few that have given rise to greater variety in their treatment. It is an extremely common affection amongst the children admitted into the Manchester Royal Infirmary; and as clinical clerk in that institution for upwards of two years, I had extensive opportunities of witnessing the different forms of treatment recommended, but frequently found that a line of treatment, which appeared singularly successful in some patients, was just as inefficacious in others. This discrepancy no doubt arises from our imperfect acquaintance with the pathology of the disease; also, in a great measure, from a want of attention to the condition of the patient, and the stage of the complaint when the remedies are applied. Looking over the cases that have come under my notice, I have generally observed that where the disease was recent, and no means had been adopted for its removal, the convulsions have been attended with derangement of the alimentary canal, as evinced by capricious appetite, constipated bowels, with scanty and scybalous evacuations. When the disease had been of longer continuance, and allowed to go on uncontrolled, in addition to the derangement of the stomach and bowels there has been more or less disturbance of the cerebro-spinal system: whilst the cases which had existed some time, and where the usual remedies had been resorted to, the general health was improved, but there was only partial mitigation of the convulsions.

These remarks tend to prove the truth of Dr. Hamilton's view of the nature of chorea—that debility and spasmodic action, previous to his time so much insisted on, are not its leading

characters, but that it depends upon a prior derangement of the stomach and bowels. In some instances this doctrine is very probably correct; but there is generally a predisposition to the affection which, as Cullen well expresses it, depends on a state of mobility in the system, that renders the body so excitable as to cause it to be readily affected by any irritation applied to it. One of the laws regulating nervous actions is, that its irritability is increased in proportion as its energy is diminished: consequently we find that the peculiarity of constitution in childhood renders the nervous sensibility so predominant as greatly to conduce to the development of this and other convulsive diseases; just as a relaxed and debilitated frame in adults produces a disposition to the nervous temperament, and makes them so highly sensitive to the actions of stimuli, both physical and moral. On this account we frequently find chorea connected with debilitated and relaxed habits, especially in those who, from their humble circumstances, have been accustomed to scanty and poor diet, and also of its more frequent occurrence in females than males. In such individuals we may readily conceive how any of the exciting causes of chorea may occasion the disease. The difficulty consists in ascertaining the exact seat of the affection, increased as it is by the variety of opinions concerning its pathological state, owing to the fatal cases having been generally complicated with other diseases.

The influence of habit in prolonging nervous complaints is very remarkable, and few diseases appear more affected by it than chorea; for in most of the obstinate cases which have resisted the various forms of treatment, there being no organic derangement, and the general health good, there can be little doubt that the convulsions remain almost entirely from habit. The conducting power of the nervous filaments being increased with the frequency of their excitement, these convulsions are continued from the slightest cause, just as in lively persons, when speaking, the movements of their hands are repeated on the least occasion. In fact, their frequent occurrence generates in the muscles a great aptitude to their repetition, as practice induces a facility in performing dexterous mechanical opera-

tions: thus a habit is acquired which assists the power of the original cause, and continues the convulsions a considerable time after the cause has been removed.

The tendency to imitation in children must also operate in keeping up that chain of actions in the body which has so long existed, whilst the absence of the "vigour of manhood" renders it extremely difficult for the child to exert himself in endeavouring to control the affected muscles. A similar condition may occur in mature age, in consequence of the balance and harmony of the functions of life being enfeebled and less vigorously performed, from a want of energy in that resilient power which enables us to bear the varied exertions of youth, acting also with such surprising vigour in restoring us to health after the depression of a severe illness. When, therefore, any of the ordinary powers destined to preserve the equilibrium between sensation and motion are disturbed, we may easily understand how the influences of habit and imitation may operate in prolonging this affection, by rendering the different sets of muscles independent of the will, which were previously of a voluntary character. If the automatic movements thus induced are not early checked, there will be some difficulty in subduing them, as we experience in attempting to avoid habits unconsciously fallen into, when the body is in a state of health. It was evidently with the intention of overcoming these influences that Dr. Darwin (*Zoonomia*, vol. ii. p. 506) suggested we should make perpetual, slow, and repeated efforts to move the limb in the designed direction, in expectation of the same good effects which follow such efforts in stammering: and Dr. Mason Good (*Study of Medicine*, vol. iv. p. 472) remarks, "it is very possible that, in some instances, a long and punctual discipline of the affected limbs, where the disease is not very severe, to regular and measured movements, may progressively recal them to their wonted order and firmness." The effect of dancing and music in curing the original chorea Sancti Viti, by diverting the automatic movements to others more regular and under the control of the will, ultimately breaks through a habit produced generally from imitation, and some defect in that power which keeps

the muscular system in its normal state of tension.

In old-standing cases, where the will can check the convulsions, but only so long as it is directed for that specific purpose, these means may occasionally be of service; but from the difficulty of keeping up their effects a considerable time must elapse before a cure can be established. To obviate this inconvenience I was led to try the experiment of confining the affected limb in splints, having frequently observed, in those instances where the convulsions had continued in spite of all remedial means, that if the patient's attention be directed to the deranged muscles, as for instance when in the hand and arm, causing him to grasp the sides of a chair, the motions comparatively cease; and this, when frequently repeated, proved a useful auxiliary in removing the disease.

Upwards of two years ago a case came under my notice where the convulsions had existed in the hand and arm for six months, though a variety of means had been adopted for their removal: believing them to depend on habit, from the control the patient had over the motions, and his apparently excellent health, I had recourse to the splints. For the first few days the twitchings, from their violence, caused some difficulty in keeping the splints firm, but they soon diminished in force, and in three weeks had entirely disappeared.

I have tried the same treatment in four other cases. In three, after attending to the bowels, I applied the splints, and continued them until a cure was established, which occupied in none more than a month. The convulsions were confined to one of the upper extremities, with slight dragging of the leg of the same side; but as the symptoms left the arm, the power over the leg returned.

The other case occurred in a youth fifteen years of age. The convulsions were more severe, and rendered it extremely difficult to keep the splints firm with an ordinary bandage: to obviate this inconvenience, I used the apparatus recommended by Velpeau for fractures, with the addition of small splints to keep the limb extended and at rest during the consolidation of the apparatus. This was removed in a week to allow of exercise; and the severity of

the convulsions being subdued, a common bandage and splints were again used. Though the convulsions affected both arm and leg, and splints were only applied to the former, the boy had recovered the use of both extremities in six weeks.

We see the same effects produced in the worst forms of chorea, where the convulsions are so severe that the patient has to be held down in bed; whilst the restraint is continued the violence of the motions is soon sufficiently relieved to enable the child to walk; but when it is removed, a length of time frequently elapses before a corresponding improvement is noticed.

In each case, considering the affection to have originated from some irritation in the alimentary canal, as hardened faeces, &c., I began with the administration of purgatives, repeated during the progress of the complaint as they were required; and whilst the splints were had recourse to, small doses of carbonate of iron were given to improve the system. Every three or four days the splints were removed, and the limb exercised, to prevent stiffness of the joints, and to assist in recovering the power of the will over the affected muscles. When they were discontinued, periodical exercise and the cold bath were used to re-establish the necessary vigour of the frame, and thus prevent a return of the disease, which not unfrequently occurs.

From what has been stated, it might be inferred that this plan of treatment is chiefly applicable to those cases where the disease exists almost solely from habit. By considering the general principles of physiology, we shall find that it may be used with advantage in recent cases, after the exciting cause has been removed, being peculiarly adapted, by allowing of the regular application of exercise and rest, for restoring the affected muscles to their healthy condition, just as sleep recruits the faculties of feeling and motion, wearied by the exertions of the day. For we are well aware that muscular energy depends on the contraction of the muscular fibres having intervals of relaxation; that in proportion as their action is increased and accelerated, subsequent rest is required to restore the same quantity of power that has been consumed; and that, by the regular alternation of exercise and

rest, power is acquired and sustained. On the contrary, if their action is prolonged, or too frequently repeated, their power of contraction is diminished, and, for a time, no effort of the will can restore it.

This is familiarly illustrated in severe and old-standing cases of luxation, where, by long and continued extension of the limb, the muscular energy becomes exhausted, and the bone is readily replaced. We know also that rest does not restore a part seldom brought into action in the same proportion as when it has been accustomed to regular exercise; and if uncombined with exercise it weakens it. A certain degree therefore of excitement and rest is necessary for the support and increase of the muscular energy. These facts are well exemplified in squinting, and had they been attended to in the early treatment of that affection would have prevented the necessity of having recourse so frequently to the lately discovered and ingenious operation; especially in those cases arising from imitation, or where the tendency to it is first produced from the nurse carrying the child in one position, or from allowing some part of the dress to interfere with the axis of vision. The consequence is, that the axis of one eye is directed to some prominent object out of the field of vision of the other, which being frequently repeated destroys the harmony between the two eyes: the one most exercised acquiring strength, the other, from want of it, becoming weaker. By this means the eyes are adapted to vision at different distances, which, if not checked, renders the faulty eye perfectly useless. So far as my experience goes, it is in cases thus produced that the operation appears to have been most successful. If, however, in the early stage of the affection, a plan of treatment had been adopted in accordance with the above principles, a cure might have been established without having recourse to the knife.

The same remarks are applicable to those cases of spinal curvature depending on muscular contraction which have received partial benefit from division of the affected muscles. If, in the commencement of the complaint, instead of rest and the recumbent position (the means formerly adopted in almost all cases of spinal distortion), the individual had been placed under the influence

of Calisthenic exercises, a more effectual and permanent cure would have been produced than we can ever expect to obtain from the operation.

The value of exercise in subduing those diseases whose duration and intensity are increased from habit, is also well shewn in stammering, which frequently depends on a want of influence of the will over the muscles of respiration: or, as a writer in the *Gazette Médicale* observes, "Its essential character consists in a convulsive condition either of a tetanic or choreic character of the respiratory function, the effect of which is either to disturb more or less, or altogether prevent, the articulation of sounds. What takes place in the lips, tongue, and throat, is altogether accessory, and according to which of these parts is chiefly affected the different varieties of the infirmity are produced."

—Johnson's Review, 1839. The accuracy of any theory concerning a disease is best tested by its effect upon the treatment. Now of all the numerous methods proposed for the cure of stammering, those are the most successful which are founded on the above views. Thus it has been long known that by taking a deep inspiration at the commencement of each sentence, and marking the time in speaking by regular movements, as in music, stammering may be cured. But these two means, simple as they appear, are very difficult to bring into operation, especially in children, for reasons previously mentioned. Sometimes spontaneous cures are said to take place, as age advances; but I believe that upon careful inquiry they will be found to have depended in a great measure on the individual's own exertion in overcoming the affection. It is, then, with the intention of increasing the influence of the will over the affected muscles, that gymnastic exercises have been so strongly recommended. "Indeed," as the above mentioned writer remarks, "it has been by their influence in regulating the act of breathing that the efficacy of the various means which have been recommended and found useful, in the treatment of stammering, is to be accounted for. In this way the practice of declaiming on the sea-shore, with a pebble in his mouth, cured, it is said, Demosthenes of old. As a further illustration of habit in prolonging disease in nervous and excitable indivi-

duals, I may mention that one of the children, previously to the attack of chorea, had a very obstinate cough, which seized her in paroxysms not unlike the whooping-cough. After being under treatment for some time, with but slight improvement, I ascertained that the attack usually came on when her father entered the house to his meals, and that when she was suddenly surprised it frequently ceased. I accordingly ordered some nauseous draught to be given whenever she coughed. In six days it was reduced to a slight hacking, which very soon disappeared. Other instances of the effect of habit in protracted diseases might be mentioned, but the object of this communication is chiefly to direct attention to the treatment of chorea.

The plan recommended may be easily combined with the means usually adopted, viz. purgatives and tonics. The former will remove any irritative matter that may be collected in the alimentary canal, and regulate its function: the latter will strengthen the system, and assist in correcting that irritable condition of the body which has rendered it prone to the affection; whilst the splints, by allowing of the regular alternation of rest and exercise, will restore the influence of the will over the affected muscles, also break through that habitual disposition which nervous and spasmodic actions are so liable to produce.

Of course the splints can only be used when the disease is confined to one or two extremities. When the whole body is affected, some other plan must be adopted. In the severest cases, as I have already stated, the violence of the convulsions is soon subdued by tying the patient down in bed with the straight-waistcoat. Perhaps if this remedy was continued for a longer time, the rest and restraint may sufficiently overcome the severity of the affection to permit the application of the splints.

The comparative infrequency of chorea in private practice must be my apology for this premature communication. Should any of my professional brethren be induced to try the means suggested, I should be obliged if they would favour me with their results*.

* It would be premature to make any remarks on the operations recently recommended for the cure of this affection, until surgeons of known reputation shall have fully investigated them.

CASES, WITH OBSERVATIONS.

By C. M. DURRANT, M.D., Ipswich.

[For the Medical Gazette.]

CASE I.—*Pneumonia, with secretion of air into the cavity of the pleura.—Recovery.*

L. D., æt. 34, of leucophlegmatic habit, after exposure to cold, was seized with rigor, followed by the usual symptoms of acute pneumonia in the lower lobe of left lung. On examination, the general and auscultatory phenomena were well marked, the disease having reached the stage of hepatisation, around the margin of which the existence of crepitation further indicated its progressive extension. He was twice bled from the arm, leeched, put on the antimonial treatment, and subsequently blistered. These remedies quickly relieved the more urgent symptoms; respiration was gradually returning in the diseased portion of lung, when, from a slight indiscretion in diet, or from some unknown cause, the disease relapsed with a considerable aggravation of the symptoms.

The dyspnoea was very urgent; the pulse 96, and small; cough very frequent, and hacking; expectoration in small quantities, of a yellowish-green colour, muco-purulent, and very offensive; constant pain in, and total inability of lying on the affected side: on percussion a tympanitic clearness was elicited between the fifth and seventh ribs of same side; respiratory murmur at this spot inaudible—in other portions of lung natural, with an occasional large mucous rhoncus: distinct bronchophony, almost amounting at times to pectoriloquy, over diseased portion, heard both anteriorly and posteriorly. A bellows sound was now audible with both strokes of the heart, but did not extend widely over the chest, and existed only during one day.

He was again put on the antimonial treatment without relief; the symptoms somewhat improved, but the cough, pain in the side, and foetid expectoration, still continued; the pulse ranging between 90 and 100, small and irritable. The stethoscope indicated the disease in the same stage, but now become latent, and at this period was heard beneath the angle of left scapula imperfect ægophony.

Local depletion by leeches, followed by a blister, was again had recourse to; the mercurial treatment was now substituted for the antimonial, in combination with digitalis, Dover's powder, and the iodide of potassium. The mercury (Hydrarg. c. Cretâ) rapidly affected the system, producing considerable tenderness, and finally ulceration of the gums, a coppery eruption on the legs, and

subsequently salivation. Under this treatment the symptoms gradually subsided, the ægophony merging into bronchophony, while the natural vesicular murmur was heard progressively resuming its distinctness throughout the diseased portion of lung. From this period the patient slowly recovered.

OBS.—Without entering in detail on the individual pneumonic symptoms which presented themselves in the above patient, I have nevertheless deemed it a case of considerable interest, and one prompting a few remarks both in reference to the symptoms and treatment. Previous to the relapse, the disease presented no feature worthy of note: subsequently, however, we find a few points to which especial attention may be directed.

First, the expectoration. This, in all cases of pulmonary disease, is a symptom of decided value, and one requiring daily and careful examination. The expectoration in pneumonia, as stated by most authors, is considered pathognomonic of the disease: that such is the case when coexistent with other general and stethoscopic phenomena, I admit; but, as in the present instance, and in many others, as is well known to the practical observer, it is liable to frequent diversities, both in colour, quality, and odour. In the present case, the greenish muco-purulent sputa, with the faintly gangrenous odour, were of importance, as indicative of severe pneumonic disease, with accompanying bronchitis, and an evident tendency to gangrenous degeneration.

The next point of interest is the tympanitic sound as elicited on percussion over the seat of the disease. This phenomenon was first pointed out by Dr. Graves, of Dublin; in whose case it evidently proceeded from an effusion of air into the serous cavity, generated by secretion. That such was the case in the present instance I am fully satisfied; and from its position over the solid portion of lung, we obtained at the same time the two somewhat opposite signs; viz tympanitic clearness on percussion, and resonance of voice, with absence of râle or murmur on auscultation. The appearance of this preternatural clearness, as usual in these instances, was sudden; but its subsidence, contrary to the ordinary termination as remarked by authors, was gradual. That it was not stomachal

clearness is evident, from its situation as well as from the differential sounds produced by percussion. In this case I fully verified the remark made by Dr. Stokes, when alluding to the sound caused by a distended stomach, and that by an accumulation of air, who styles the one "a tympanitic dulness;" the other, "a tympanitic clearness."

These cases have been confounded with abscess, fistula, &c.: by marking the position and extent of the clear sound, together with the absence of the other signs of these lesions, we shall, I think, find no difficulty in establishing a correct diagnosis.

In the above patient a distinct bruit de soufflet accompanied both sounds of the heart, but existed only during one day. A similar circumstance is noticed by Dr. Graves as occurring in the case of tympanitic clearness alluded to above. In that case the bellows sound was not confined to the region of the heart, but was audible over the front of the chest. In my patient, on the contrary, it was limited to the cardiac space. Dr. Graves mentions another symptom as occurring in the same individual; viz. throbbing of the chest, synchronous with the heart's action: this phenomena did not obtain in the case under consideration.

Dr. Stokes attributes the bruit de soufflet in Dr. Graves's case, to pericarditis, or endocarditis, rendered latent by being complicated with pneumonia. In the foregoing case I attributed the bellows sound to increased irritability of the heart, in the same manner as is so frequently heard in nervous irritability, functional affections of the organ, &c. and unconnected with existing disease in this viscus.

The last symptom I shall notice is the occurrence of the ægophony. It is now admitted by the greater number of practical authors on thoracic diseases, that the signs of ægophony and pectoriloquy are, if taken singly, and without comparison, the two most fallacious of all the auscultatory phenomena. These signs are only valuable as occurring singly and without coexisting symptoms in the opposite side. The necessity of comparative examination in all stethoscopic investigations cannot be too strongly enforced, since it is by comparison alone that we are enabled to form anything like a just estimate of

the nature, extent, and progress of the disease. In some individuals, for instance, in perfect health, there exists loud resonance of voice under both clavicles: again, instances have been recorded in which the voice beneath both scapulae constantly preserved the ægophonic character. Such being the case, no prudent physician, however versed in stethoscopic practice, will venture to pronounce his diagnosis, without due comparative examination.

Ægophony is occasionally heard also, as stated by Stokes, and others, during the resolution from hepatisation, as well as in the stage of purulent infiltration. In the present instance the ægophony was evidently the result of sudden but slight effusion; since, immediately on the detection of the ægophony, the patient admitted he could *not* lie easier on the affected side: still, however, on attempting to recline on the healthy side, there was neither dyspnoea, nor any aggravation of the more prominent symptoms.

That the resolution of solidity is not always accompanied by a return of the crepitating râle, the above case demonstrates: this fact, though contrary to the statement of Laennec, is noticed by Dr. Stokes in his valuable treatise on diseases of the chest. In the above patient, the *rhonchus crepitans redux* of Laennec was distinctly audible previous to the relapse: subsequently to this occurrence, however, although the solidity has slowly and progressively resolved, no rhonchus of any kind, indicating this change, could be detected, but a gradually increasing return of the natural vesicular murmur.

Contraction of the chest is not an unfrequent occurrence during the progress of chronic pneumonia. It appears to exist principally in cases in which the lower lobe of the lung has continued for a considerable period in an indurated and impervious condition. In the preceding case the chest was measured at the time of commencing the mercurial treatment, when the diseased side, at its lower portion, measured an inch and a half less than the opposite one. During convalescence it was interesting to observe the progressive expansion of the affected side, in perfect accordance with the gradual reappearance of the respiratory murmur.

In the treatment of acute pneumonia, there appears little diversity of opinion

respecting the utility of blood-letting; but in reference to the period for abstracting blood, the quantity drawn, and the repetition of the measure, practitioners are by no means so fully agreed. Without entering on the various opinions of authors, I shall merely briefly state the summary of my own views in reference to general and local blood-letting.

In an attack of acute pneumonia, if we are fortunate enough to see the patient at the very onset of the disease, even before the crepitating râle is fully developed, and local excitement of the organ is the chief symptom, this undoubtedly is the period in which venesection will produce the most decided impression; next to this, and the one in which we are most frequently called upon to act, is during the stage of sanguineous congestion.

At the first bleeding I have seldom found it necessary to abstract beyond twelve to sixteen ounces: this measure I generally follow by the application of at least a dozen leeches, which, in this instance, I prefer to cupping: on their removal a large cataplasm applied over the bites affords in general much relief.

A repetition of the venesection will be called for, should the symptoms, after the lapse of some hours, still continue with equal intensity: from nine to twelve ounces in the second bleeding will suffice. Seldom is it necessary, in my opinion, to repeat the *general* blood-letting more frequently than as above directed: not so, however, with respect to the local abstraction of blood by leeches, which should be repeated daily, or at intervals of two or three days, until, directed by the stethoscopic and general signs, we are convinced of a permanent mitigation of the symptoms; even should we, as is frequently necessary in the adynamic or typhoid variety, be compelled at the same time to support the strength with food and even stimulants.

After bleeding, the next most important remedies to be considered are antimony and mercury; these, with venesection, have been not inappropriately termed the "physician's sheet anchor." In the selection of either of these remedies, very much must doubtless depend on the peculiar features and circumstances of the case. If the

patient be young and vigorous; if the disease be recent, and assume an inflammatory type; if the crepitating râle be still audible, either generally, or around the solidified portion, indicating an extension of the disease, then in general we shall find the antimonial treatment attended by success. But if, on the contrary, the case be one of relapse, and especially if it have in the first instance been treated by antimony; if the hepatization remain stationary, without signs of resolution; if the powers of life be low, or the disease be complicated, or assume a typhoid character, in these cases the mercurial treatment is decidedly to be preferred and adopted. The manner in which the patient has borne the previous bleeding, added to the firmness of the coagulum, will afford material assistance in the choice of the remedy. My experience does not, I confess, bear out the utility of prescribing such large doses of tartar emetic as are recommended by many authors. I have seldom found it necessary to order larger doses than one-third to half a grain repeated at intervals of three or four hours; the tolerance has soon been established, and the disease in general yielded readily. In the adoption of the mercurial treatment, the system should be affected as early as possible, and in the mildest manner: small doses of calomel and opium, or Hydr. c. Cretâ, with Dover's powder, will in general fulfil every intention required, the absorption after bleeding being usually rapid and easy. In the use of this remedy, as of the former, I am averse to the heroic doses of ten and twelve grains of calomel, as recommended by some writers on pneumonia.

Dr. Christison, in a recent paper*, strongly recommends the revival of the practice of treating acute internal inflammation by full doses of opium after blood-letting.

The adoption of counter-irritation, and especially blistering, has given rise to occasional discussion, and some difference of opinion. Without analyzing the views of authors on this subject, I may briefly state, that after the removal of the inflammatory symptoms, when the pulse is soft, and the

* Edinburgh Monthly Journal of Medical Science for Feb. 1841.

pungent heat of skin is somewhat subdued, and especially in all cases of typhoid and complicated pneumonia, the application of a blister is attended by the happiest results. Large blisters, in the first instance, are preferable to small, since the irritation produced by them is by no means commensurate with their size, and the sanative effect is much increased. When, however, the disease has become latent, or chronic, the repeated application of small blisters is of the greatest service in promoting its resolution.

During convalescence I often find very considerable benefit accrue from ordering the entire affected side to be sponged night and morning with a turpentine liniment, a portion of which being absorbed, acts with double efficacy.

A few words on diet and regimen during convalescence, will close the remarks I have to make on the treatment of this affection. Few diseases require the vigilance of the physician more constantly during convalescence, in reference to diet, than pneumonia, since the slightest indiscretion, on the part of the patient, serves in many instances to fan the waning disease again and again into an active state. After the reduction of the inflammatory symptoms, the food must at first be strictly farinaceous, to which we may add a light vegetable diet of asparagus or sea-kale: if the desire for food progressively increase, light puddings, with the weakest mutton or chicken broths, may be allowed. From this we may ascend the scale to boiled sole, haddock, or whiting; mutton, beef, and game, are the most digestible of meats; after which the patient may gradually return to his usual fare. The same cautions must be strictly adhered to in reference to tonics and stimulants. The temperature of the sick-room should never exceed 60° Fahrenheit; flannel should be worn next the skin on recovery; and, as early as convalescence permits, change of air, if compatible with the patient's circumstances, will prove of especial benefit. I need scarcely add, in cases of latent or chronic pneumonia, the necessity of constant and accurate stethoscopic exploration, with a view to guard against and detect the earliest appearance of tubercle, especially if phthisis be hereditary in the family.

CASE II.—*Hydruria, with deposition of Phosphates.*

Jane Barker, æt. 38, residing in the country, married, has had three children. Complained, on application, of general debility and depression of spirits, want of sleep, with great disinclination for any kind of exertion; almost constant pain in front part of head, together with occasional severe pain in right hypochondrium, not increased on pressure, with considerable weakness and "gnawing" sensation in loins, pubes, and thighs. Her expression was care-worn and anxious, with an evident tendency to view all her affairs in a dark light.

States she is the subject of slight prolapsus uteri, with more or less leucorrhœal discharge. Catamenia have lately been very irregular, sometimes returning at the fortnight in profuse quantity, amounting to menorrhagia; at which period she suffers pain, but passes no clots; has almost constant desire to evacuate the bladder. Complexion sallow; skin dry and unperspirable; eyes dull and heavy, the lower lid bounded by a broad, dark, semicircular line; some cough, with palpitation of heart; pulse 86, small, and feeble; tongue moist, with white coating; clammy unpleasant taste in mouth; no thirst; appetite much impaired and variable; occasional vomiting; bowels constipated; urine limpid, in large quantity, of a pale-straw colour, becoming slightly flocculent on cooling, and forming a pellicle on the surface; does not affect litmus paper; sp. gr. 1.005; not coagulable by heat or nitric acid. The quantity of urine voided in twenty-four hours could not be ascertained, on account of the patient residing in the country. On examining the chest, respiration was normal, but weak; action of heart irritable, free from adventitious sound, and otherwise natural; right lobe of liver evidently somewhat enlarged.

The indications for treatment being clearly the improvement of the general health, after premising the use of the perinæum cushion and bandage (as recommended by the late Dr. Hamilton, of Edinburgh,) for the prolapsus uteri, she was ordered a stimulating embrocation to be applied to the side night and morning, and the following medicine:—

R Pil. Rhei Comp. gr. viij.; Ex. Hyoscyam. gr. iij. Ft. pil. duæ om. n. sumend.

R Sodæ Carbon. ʒj.; Inf. Gentian c. ʒv.; Tinct. Rhei Co., Syr. Zingib. aa. ʒiv. M. sumat cochlearia duo magn. ter in die.

In a few days she reported herself better; bowels now regular, no return of menorrhagia; urine still in large quantity, and pale; sp. gr. 1.006; appetite somewhat im-

proved; has slept better; skin continues dry, harsh, and unperspirable.

Contin. Mistur. \mathcal{R} Pil. Rhei Co. gr. v.; ft. Pil. om. nocte sumend. \mathcal{R} Pulv. Ipecac. Co. gr. x.; ft. Pulv. o. n. sumend.

Did not return for some days, when she stated she felt much more languid and depressed both in mind and body, all her symptoms having returned, with the addition of a copious deposit of "white powder" in her urine, which still continued to annoy her, both by its quantity and the frequent desire to empty the bladder. On examination it was now alkaline, of the same low specific gravity, not coagulable, and the deposit soluble on the addition of nitric acid.

\mathcal{R} Tinct. Opii \mathfrak{z} j.; Acidi Nitr. Dil. \mathfrak{z} vij. M. Sumat. gtt. xx.; ter die ex aquâ. Contin. P. Ipecac. Co. om. noct.

On next application she was much improved in health, and in better spirits, though still irritable; quantity of urine decreased; sp. gr. 1.008.

Contin. Medicament. Aug. Tinct. Opii ad \mathfrak{z} ij.

From this period her health was considerably restored; she was gaining flesh and strength, and expressed herself very grateful for the benefit received. The urine still remained in somewhat abnormal quantity; sp. gr. 1.012; was ordered to continue the medicine, did not again apply, and I have since heard she "is doing finely."

OBS.—The above case affords a good illustration of the general symptoms of hydruria, coexisting with those which so frequently obtain towards the close of the menstrual secretion. The absence of thirst in the present instance deserves notice, since the desire for drinks, in all cases characterized by an increased flow of urine, is in general one of the most prominent, and frequently a very distressing symptom, especially as, in reference to the treatment, it is necessary to regulate the quantity of fluids taken, with a view to curtail the function of the kidneys as much as possible.

Another point deserving attention is the low specific gravity of the urine. This symptom remained constant, and, as far as I could ascertain (the patient residing in the country), did not vary, as it frequently does, when taken at different periods of the day.

In treating this affection the principal indications are the improvement of the general health, and the diminution of the excessive irritability which

pervades the system. With a view to the first intention the diet must be carefully regulated, no more food being allowed than the stomach will easily and completely digest; and this should be selected with reference both to lightness and nutritious quality. The quantity of fluid allowed should be no more than is absolutely requisite; and must not be permitted to be taken with a view to quench the sometimes immoderate thirst.

A warm bath taken on alternate nights, is frequently of great service. The medicines most useful in this affection are, the vegetable and ferruginous tonics, combined with opium. Where the phosphatic diathesis prevails, the dilute mineral acids, with opium, as prescribed in the above case, are especially indicated. Ten or twelve grains of Dover's powder should be taken every night at bed-time, which may be repeated with advantage in small doses during the day. The bowels must be carefully regulated by mild aperients: a combination of aloes, rhubarb, and hyoseyamus, with from half to a grain of ipecacuanha, will in general fulfil every intention. In the foregoing case the aloes, for evident reasons, was omitted. Mercurials, in this affection, are injurious. Flannel should be worn next the skin.

CASE III.—*Dysuria following an attack of measles.*

William Capper, æt. 10, from exposure to infection was attacked with rubeola in its simple uncomplicated form. In a few days, however, the symptoms assumed a considerable degree of severity, being complicated with sore-throat, and a smart attack of acute bronchitis. Complained of headache; pulse 90, small and feeble; bowels confined; tongue red at apex and edges, coated in the centre; eyes suffused; urine natural in quantity, high coloured, strongly acid, depositing a red sediment, not coagulable. Leeches were applied to the chest, general blood-letting being deemed inadvisable from the great vital depression; purgatives and diaphoretics were administered, with small doses of carbonate of soda, to neutralize the hyperacidity of the urine. Under this treatment the symptoms were speedily removed, and the patient became rapidly convalescent. Urine still remained acid. The eruption had entirely disappeared, and the case was pressing favourably, when the patient complained suddenly of difficulty in making water, accompanied with pain at the neck of the bladder, sensation of heat in the urethra,

and some pain in the lumbar region. Pulse 86, small and weak. On examining the hypogastric region, slight pain and tenderness were experienced on pressure; the lips of the urethra were swollen, and its lining membrane redder than natural; the small quantity of urine passed was of a deep orange tint, strongly acid, transparent, but depositing a little sediment; on cooling, sp. gr. 1.027, not coagulable.

Was ordered — *Hirudines* xii. *perinaeo*; subsequently to remain in a warm bath, 98°, for half an hour; *statim sumat*. *Ol. Ricini* ʒvj.; *Tinct. Opii* ℥xx. *M.* To have *Haust. Salin. Aper. c. Antim.* *Pot. Tart.* gr. $\frac{1}{2}$, *quarta quaque hora*.

Bowels were freely opened. The pubes and *perinaeum* to be assiduously fomented. Urine passed more freely, both while the patient remained in the bath, and on leaving it. Six more leeches were applied to the *perinaeum*, and the following prescribed.

℞ *Sodæ Carbon.* ʒij.; *Tinct. Hyoseyam.* ʒj.; *Inf. Sennæ Co.* ʒiij.; *Mist. Camph.* ʒiv.; *Syr. Simp.* ʒvj. *M.* *Cochl. duo mag.* 4ta qq. *hora*.

℞ *Pulv. Ipecac.* [Co. gr. x. om. noct. s.; bis in hebdom. descend in *Baln. Cal.* Linseed tea and barley water to be drank freely.

Urine now became less acid, and was passed without difficulty. Sp. gr. 1.025. Was ordered — *Tinct. Ferri Sesquichlor.* ℥ix. *ter die*, and from this period he gradually recovered.

Obs.—Difficulty of making water occurs more frequently during the progress of, than subsequent to, an attack of *rubeola*; it is an affection of much rarer occurrence than many other complications of this disease, yet at the same time one requiring vigilance for its early detection, and prompt treatment for its cure.

In the above case, the occurrence of the symptoms, and mode of attack, are well marked, together with the effect of the remedies employed. Probably, had general blood-letting been had recourse to in the first instance, on the supervention of the acute bronchitis, the dysuria would not have occurred; such, I confess, is my present opinion; but so great was the general debility and depression caused by the measles, that, as before stated, venesection at that period was not thought advisable. The cause of this affection appears to consist in an inflamed condition of the vesical mucous membrane, and espe-

cially in a congested state of the vessels of that membrane, more particularly in the portion surrounding the neck of the bladder. The irritable state of the parts renders this viscus incapable of containing more than a very small quantity of urine, and this irritation extending to the sphincter of the bladder and Wilson's muscles, increases the difficulty of making water, and strangury, or even complete ischuria, occasionally result.

In the foregoing case, the phlogistic state of the mucous membrane appears to have been of metastatic origin, for immediately on the removal of the bronchial inflammation we find an attack of a similar nature set up in the mucous membrane of the bladder.

The introduction of the catheter has been justly reprobated in the treatment of this affection; it should be used only as a *dernier ressort*, other remedies having proved ineffectual: "since then," says Mr. Syme, "the additional irritation thus occasioned is more than counterbalanced by the good effect of emptying the bladder, which, when stimulated by distention, reacts upon the spasmodically contracted muscles at its neck, and increases their resistance." If the introduction of this instrument be found necessary, its withdrawal should be immediately followed by the exhibition of an opiate enema, and after a proper interval a full dose of castor oil.

A similar treatment to that adopted in the preceding case will in general effect a cure. Blood-letting, especially locally from the *perinaeum*, hot fomentations, the warm bath, full purging, followed by saline antimonial aperients, will usually afford speedy relief, without the aid of the catheter. Should complete ischuria supervene, the *Tinct. Ferri Sesquichlor.*, administered in small and repeated doses, so as to keep up a continued feeling of nausea, is often of signal service.

A FEW OBSERVATIONS ON INSTINCT, &c.

To the Editor of the Medical Gazette.

SIR,
THE following short memoir originated in memoranda which I made whilst engaged in reading an essay, or series

of essays, a considerable time past, in *Blackwood's Magazine*, and having been then too busily occupied in other matters, I neglected and for a long time forgot the subject: the writer in "*Blackwood*" tried to prove that there were neither feelings nor sensations in the insect tribe! which strange opinions I hope to refute, although he has brought very powerful reasoning to support his side of the question.

Amongst his first and leading propositions he advances this one, which, most indubitably, if he could prove, would very soon settle all dispute in the case: "that there can be no sensation without distinct nerves of sensation." Then I answer, that if such hold good, there can be no objection whatever why the following should not be added as a counterpart of that proposition, namely, "that there can be neither motion nor digestion without distinct nerves in accordance with these respective functions." So how this dilemma is to be got clear of is rather beyond my comprehension at present; because what would become of the *Entozoa*, *Polypi*, and such like creatures, which exist in the lowermost grades of animal life? they are long well known to possess neither distinct nerves of motion nor digestion, nor in fact distinct nerves for the performance of any other living process in the animal economy. Consequently, according to the opinion brought forward above, these beings should not be possessed of either digestion or motion; but, rather unfortunately for the soundness of his deduction, these little creatures are well known to possess both motion and digestion; and on equal grounds I would conclude that they—even they, although so much inferior, so to speak, to insects—are possessed of sensation also. A German author states that in several animals, particularly among insects, an acute sense of smell seems to exist, although no part can be pointed out in the head which analogy would justify us in describing as a nose; so, of course, no distinct nerve of smell, when there is no organ apparently for it; yet notwithstanding all that, they are proved to be endowed with the function of smell.

He next advances, "that motion may be without pain, and that pain

may be without motion:" but if we apply to a living organism (any part which is sensitive in a living animal being) an exciting cause that amounts to irritation, we are reasonably to infer that pain is produced, because violent action is called forth in trying to get rid of the cause of annoyance; and how is the living being to call those parts into action unless it have some powers consistent therewith; unless, in fact, it have nerves, or something similar, whether distinct to our eyes or not? It should be recollected that the only way to account for a nervous system being present in the lowest grades of animal existence—where the most active digestion (and motion in some) go on, although neither brain nor nerves of any kind are to be found, is, that the nervous matter is combined in some hitherto unknown way with the general mass of tissues; and motion may be the more inseparable from pain, in those very classes of which he speaks, just because of the imperceptibly and inextricably close junction and interlacement, or even amalgamation, of the nervous filaments of motion and sensation. I may mention that the author to whose essays I allude has wished to be understood, if I mistake not, that the insects, &c., which anglers make use of, suffer no pain whatever—no matter their motions should indicate the contrary when placed upon the fishing-hook; and this, forsooth, by reason of his not being able to find any distinct nerves of sensation in them. Now, by parity of reasoning, I think I have shewn that myriads of animated beings should neither digest, move, smell, &c. &c.; but the conclusion of the argument is, they are found to do all these things, although we cannot see in them any distinct nerves to answer for the performance of such operations. Perhaps it may be requisite for me to premise, that in man, &c., there are distinct nerves appropriated respectively to motion—that is, to call the various muscles into action—and others distinct for sensation, which means the common sense of feeling or touch over the body; like as others distinct for vision, hearing, &c.: but we are not for a moment to infer that if this high state of organization is not

found in all animals, such animals consequently must be in complete want of certain functions or powers: no; we find the organs changed and varied almost indefinitely, to suit the adaptation for the varying circumstances, medium, and contingencies, to which each family of living beings is subjected; and although the organs may be equally changed, yet their functions are found nearly always similar.

It appears singular that any person should for an instant question the validity of the generally received fact, that insects, &c. possess the sense of touch, and if they possess that sense, which is evidenced by the application of excitable causes, as surely must pain be produced in them by subjecting them to irritating stimuli; and this is soon perceived by the violent efforts on their part, and these observations are applicable to worms, &c.

The antennæ, or feelers of insects, seem to be the very concentration, so to speak, of sensitiveness, and the sense of touch in spiders is well known to be extremely acute. Now if we were to reason in full analogy with ourselves, we would say that whatever part is highly endued with common sensation, such must in equal ratio be susceptible of pain; but there are, no doubt, great diversities in amount of sensitiveness, whether general or local; as for instance the horny cuirass of the insect compared with the antennæ; or our own teeth and nails in a diseased state compared with their healthy condition: so that a part which may have very little common sensation at one time and in one state, may soon become quite reversed; or a part which has considerable touch, and which in the healthy state may be stimulated without causing much pain, yet if it become diseased, and then stimulated, will give dreadful pain. There are other varieties of sensibility, as that of the stomach, &c.; and these vary very peculiarly, and would be unknown to us by any *à priori* reasoning; such as that in caterpillars, whereby the poison of nettles is innocuous; or that in birds, by which they can eat the berries of the mezereon.

What is instinct? It appears inscrutable. A bee returns home before evening, as his instinct directs, and

numerous other instincts the bee is well known to possess, many of which are wonderful and almost incredible; the instincts of the bee also far outnumbering those of even the elephant or dog, which must render it a problem of rather difficult solution to the phrenologist, it being a generally received opinion that the larger the encephalon or cerebral ganglion (which means the brain respectively in the upper and lower classes of animals) there will be found the more intelligence and instinct. This, however, does not always hold true, either relatively or absolutely; as instance the enormous brain of the dolphin, the canary, &c. and the diminutive brain of the wild boar, and many fish, &c., in none of which is exemplified either a great amount or marked deficiency of instinct.

If the author before mentioned do not admit such things as *feelings* in the lower tribes, how will he explain why a mouse should be frightened and horror-struck, almost out of its very existence, by seeing a serpent, although it had never seen, or perhaps *heard*, of one before? How is fear produced in him by remembering any thing hurtful? May it not be produced by instinct, as is above exemplified, and that equally as where memory suggests? There are many instinctive actions performed where memory could never have been exercised, or even almost had time to be called into action. What shews instinctive fear, as also cautious boldness, more than a flea? What could possibly exhibit more the pleasure and delight obtained by the eyes from light than a moth, as observed rushing to and gyrating round the flame of a candle with all the glee imaginable, until it become fascinated so far that it is induced to go too near, and so, through its over desire for enjoying the light, loses its life? We are not required to look on these as what, in our bounded and finite conceptions, we might almost consider mental operations; such may not be, and is not, a proper term. But we should recollect that instinct is an all but undeviating intuitive source of the motives to action in the lower grades, or rather in all grades: in some few matters purely instinctive, not even man excepted, such as the sucking of the infant, &c.; and when we descend in the scale to insects, who

have only what is termed a ganglionic system of nerves, and who have, properly speaking, no brain, and whilst we find among these little creatures the most marvellous instinctive actions—actions far more requiring, in common parlance, a brain, according to phrenological computations, than do the comparatively few instinctive operations of the generality even of the mammalia—we are obliged to stop short, and look on with admiration and amazement, because the largely-developed cerebra or brains of the mammalia are adduced as criteria and proofs of their several amounts of intelligence: then if such were absolutely requisite for the development of instinct, &c. how will it be explained that a superior and greatly extended series of instincts exist, as in the insect tribe, where there is nothing that can properly be said to correspond with the brain as it exists in mammalia, birds, &c. almost at all?

An eminent author has lately given us the following distinguishing trait, as affording a line of demarcation between instinct and reason:—"that animals acting by instinct are rarely, if ever, competent to make the most trifling changes in their modes of action, no matter what contingencies may occur to require such changes."

We must probably rest satisfied at present with respect to the amount of our knowledge in many things; and, in reference to instinct, we are totally unable to fathom what that is which is implanted in the lower grades, we should say, of all kinds in the creation, according to his kind; it is a something, we perceive, which, ordered by Almighty fiat, can, and does, continually impel to actions, either through the medium of a cerebro-spinal system, as in the mammalia, birds, reptiles, and fishes; or through what is termed the ganglionic or splanchnic system, as in insects, spiders, crustacea, worms, and mollusca; or, finally, we find it impelling to action where no nervous system of any description can, apparently, for so far, be made visible to our eyes, even upon the field of the most powerful microscope, aided by the most minute dissection—as in the zoophytes.

How else could we explain the actions of those last-mentioned existences, whose organs and functions are so simple, so few, and so uncomplicated;

consequently termed the lowest in the gradation of animal organization?

Or how should we be competent to explain the state of desperation exhibited by the fly at the sight of a spider? or the manifest delight of a geometric net-working spider when engaged whirling with rapidity round a butterfly, encircling and fettering its wings by the coils of the gossamer-like thread thrown around them?

Or, to take an instance in a higher range, how could the greatest philosopher ever attempt to give a rationale for the apparent joy, as exhibited by a young turkey, just escaped that instant from its shell, seeing a fly, and no sooner seeing than darting at and swallowing it? Than this there could scarcely be adduced a more trite and positive specimen of pure instinct; and many such, if necessary, might be added, where the actions could not possibly result from previous impressions dwelling in the memory.

I find I have not yet exhausted all my notes on the subject, but shall, for the present, come to a conclusion: it is difficult bringing such matters down to a state fitted for the general reader, yet I hope, to a certain extent, I have succeeded, as I have excluded some profound and debateable physiological points altogether, which it were scarcely possible to render intelligible, excepting to those initiated in the observational sciences.

I hope it will now be seen and granted that insects, &c., although not possessed of distinct nerves, yet may have the faculty of touch, and, having that, must, reasoning consequentially, be liable to pain. We have also shewn that they most unequivocally do exhibit a variety of feelings or emotions, or whatever metaphysicians may define them; and what reason is there why these should not be implanted in them, when we find that in many there are the most truly wonderful indications of what might be termed intellectual instincts, as in ants, bees, wasps, spiders, &c., and why should we deny to them emotional instincts?—I am, sir,

Your obedient servant,

GEORGE HILL ADAMS, M.D.E.

Chichester Street, Belfast,
Nov. 10, 1840.

ON STAMMERING,

AND THE METHODS PROPOSED FOR ITS
REMOVAL.

BY EDWIN LEE, ESQ.

[For the Medical Gazette.]

PREVIOUS to entering upon the consideration of stammering, I shall briefly notice some points connected with the functions of the voice and speech.

The first condition necessary for the production of the voice is that the air contained in the lungs should be carried, by the action of the muscles of expiration, against the vocal chords; during its passage through the larynx; but as this takes place in breathing without sound being occasioned, the action of the small muscles which enter into their composition, under the influence of the will, is a condition no less essential than the former. The quantity of the air, the greater or less rapidity with which it strikes the vocal chords, and the varying degrees of tension or contraction of these latter, are the circumstances which cause the innumerable modulations of sound in speaking, singing, and other exercises of the voice.

This function may then be considered as intimately connected with, and as superadded to, that of respiration; and its performance depends entirely upon the lower vocal chords, as, if the recurrent or inferior laryngeal nerve, which supplies them with nervous energy, be divided or paralysed, the voice is lost, which is not the case when the upper vocal chords are deprived of power by the lesion of the superior laryngeal nerves, which, as well as the recurrent, are branches of the eighth pair. The voice may also be impaired or lost by lesions of the brain affecting the origin of the nerves, or by moral impressions and other causes which interfere with the exercise of volition, of which the nerves are merely the agents or conductors, as far as muscular action is concerned; and it is liable, as is well known, to a variety of alterations, according to the state of excitement or depression of the cerebral faculties, as illustrated by the various passions and emotions—joy, anger, fear, sorrow, &c.

Of the cerebral nerves, some are exclusively agents for the transmission of special sensation, as the first and second pairs, and a portion of the

seventh (which, however, is essentially a separate nerve) for smell, sight, and hearing. Others serve solely for the transmission of volitions, and the performance of muscular action, as the third, fourth, sixth, a part of the seventh, and the ninth pairs; while others again, as the fifth and eighth, are agents both of sensation and muscular motion.

It is scarcely necessary to repeat the obvious truism, that speech cannot be produced without the voice; but the voice may exist, and indeed does exist in the greater number of animals, without speech, which is peculiar to man, being bestowed upon him for the expression of his thoughts and ideas. Idiots, who have no ideas to express, are generally dumb, or can merely articulate a few words or phrases without meaning, or which they know will cause their ordinary wants to be supplied, but they are incapable of conversing. Speech, however, is not a natural gift, but is acquired by education; hence those born deaf are also dumb: and instances are on record of individuals who have been found in solitudes far from the haunts of men, who, though not deaf, were dumb, and had acquired the voice of animals with whom they had associated, but who were afterwards taught to speak. Dumbness, therefore, does not consist in the absence of voice, but of speech and the deficiency of ideas, as most dumb persons can utter a variety of inarticulate sounds: but it by no means follows that a facility in speaking necessarily exists in proportion to the quantity of the ideas or the power of the mind. Many men of genius and great imaginative powers are but little talkers, and some not unfrequently experience difficulty in expressing their thoughts on any particular subject; while empty-headed fellows are frequently very loquacious, and, like Gratiano, "speak an infinite deal of nothing;" for—

"Talking is not always to converse;
Not more distant from harmony divine,
The constant creaking of a country sign."

And, as has been observed by a powerful writer, a great fluency of speech is frequently owing to a scarcity of matter and a scarcity of words, "for whoever is a master of language and has a mind full of ideas, will be apt in speaking to hesitate upon the choice of both; whereas common speakers have only

one set of ideas, and one set of words to clothe them in, and these are always ready at the mouth: so people come faster out of a church when it is almost empty, than when a crowd is at the door*." On the other hand, many highly intellectual men are great talkers, and not unfrequently jest or talk nonsense by way of relaxation: so that silence and gravity of demeanour are not always a proof of superior wisdom, though they are frequently considered so by the multitude, and are in consequence sometimes assumed by persons who either have nothing to say, or who wish to impress others with a sense of their superiority†.

"Since silence seems to carry wisdom's power,
Th' affected rogues, like clocks, speak once an hour‡."

Such individuals are likewise noticed by Shakspeare, as the sort of men

"Whose visages
Do cream and mantle like a standing pond,
And do a witful stillness entertain,
With purpose to be dressed in an opinion
Of wisdom, gravity, profound conceit."

The immortal bard adds—

"I do know of these
That therefore only are reputed wise
For saying nothing."

A complicated mechanism is required for the correct articulation of words or speech, in the production of which various parts are concerned, which should be in a perfect state, and act in harmony. If a portion of the upper or lower jaw, or if the bony palate, be destroyed, if many of the teeth be lost, the speech will be more or less affected. A similar effect will ensue if the soft palate be perforated by ulceration; if the passage through which the air has to pass be narrowed, or its sensibility increased by inflammation or swelled tonsils; if there be paralysis or other serious lesion of the muscles of the cheek, lips, or tongue, though this organ may be in great part extirpated without speech being lost§. Now, the

* Swift.

† "Reserve is no more essentially connected with understanding, than a church organ with devotion, or wine with good nature."—*Shenstone's Essays*.

‡ Dryden.

§ A case is recorded by Tulpus (*Observationes Medice*), which is quoted in the *Dictionnaire de Médecine*, of loss of speech after extirpation of one-half of the tongue, but in which speech was restored after an interval of three years, in consequence of the fright caused by a storm. Here the moral impression from the operation doubtless occasioned aphonia.

pharynx, fauces, the soft palate, the uvula, the tonsils, derive their nervous influence from the eighth pair (which we have seen supplies also the laryngeal muscles), by means of the glosso-pharyngeal branch (which, however, is considered by some anatomists, Gall and Bichat, &c. as a distinct nerve), by means of which their muscles contract on the application of their appropriate stimuli—food for deglutition, the air for the formation of speech, &c.—being but partially under the control of the will as far as other actions are concerned. This nerve likewise endows these parts with their peculiar sensibility, and also supplies the muscles of the posterior part of the tongue, being finally distributed to the papillæ on its surface; and is in all probability not only the nerve of taste, but is likewise concerned in some of the movements of the base of the tongue, the associated action of which is necessary in speaking, in deglutition, &c.* It forms innervations with the respiratory nerves, and with the sympathetic, participating in their healthy and disordered conditions. The tongue is likewise supplied by the fifth pair for common sensation, and by the ninth, which, being purely a nerve of voluntary motion distributed to the muscles, brings it more directly under the control of the will than those parts which are supplied by the glosso-pharyngeal; as may be seen on comparing the flexibility, rapidity, and great variety of the movements of this organ, with the limited action of the fauces†. The same remark applies to the muscles supplied by the portio dura, which is also exclusively a motor nerve.

In the article *Bégaiement*, contained in the "*Dictionnaire de Médecine et Chirurgie pratique*," (which I read two or three days ago), I am happy to find an opinion which I expressed on the cause of stammering at the Westminster Medical Society, corroborated by the high authority of M. Magendie, who says, in the above-mentioned article—

* Galvanism of the trunk of this nerve, after death, produces contraction of the muscles of the fauces, &c. which it supplies.

† The size of the lingual nerve has been found to vary in a direct ratio to the quantity and rapidity of the movements of the tongue, either for mastication, the prehension of food and drink, as for the exercise of the voice. It is consequently larger in dogs and cats than in the ruminating animals and in the rodentia. — *Sarlandière, Traité du Système Nerveux*.

"Of the muscles which serve for articulation, some are subject to the will, as those of the lips and cheeks; those which carry the point of the tongue upwards or forwards, to protrude it out of the mouth; and those which draw it back. But the other muscles of the tongue, viz. those which carry its root upwards, downwards, or backwards; the muscles of the velum palati, those of the pharynx and of the larynx, are only incompletely under the influence of volition,—thus, what a great difficulty most persons experience when requested to show the physician their throat or fauces. We may well tell them to depress the tongue, because it hides the tonsils; they make many efforts, and it is more by chance than by a true influence of the will that the desired action is obtained. If they be required to raise the velum palati, the will is most frequently powerless: and it would fail entirely in the attempts to contract separately the muscles of the pharynx or larynx. The muscular organs only act in a complete manner to attain a certain end—deglutition. In order for deglutition to be performed there must be something to swallow, even if it be only a little water or air. Thus, in one point of view, the muscles of deglutition are not subject to the will.

What has been said of deglutition is applicable to other phenomena which take place in the mouth. Nothing is so simple as to gargarise, to spit, &c.; but in these instances, as in swallowing, we attain the end by means of organs which serve us, without knowing exactly the part which each takes in the action. It is the same with respect to the production of sounds in the larynx; and in speaking we form the voice, we articulate, without knowing exactly what movements take place either in the larynx or in the mouth. There are numerous vocal phenomena of which the mechanism is yet far from being known to the physiologist. We will the end, and we attain it; that is all."

In other parts of the body, the movements of which are completely under the influence of the will, as the trunk and extremities, a certain degree of harmony, or unity of action, must exist not only between certain sets of muscles, but also between muscles and their antagonists. When the flexors, for

example, are employed in the performance of an action, their antagonists are not altogether relaxed, but serve to modify the muscular contraction, in the appreciation of the degree of tension and resistance, in the preservation of the equilibrium of the body, &c. as seen in the instance of rope-dancing and other feats of agility, in which this harmony is carried by education and habit to the highest perfection; whereas the deficiency or want of it is illustrated by awkwardness, and in cases of drunkenness or chorea. Let two boys attempt for the first time to slide upon the ice, or to skate; one will preserve his equilibrium tolerably well, while the other will probably fall down every two or three minutes. Or, let them be taught to dance or fence; one will acquire easy and graceful movements without difficulty, while the other will probably retain much of his awkwardness, notwithstanding the instructions of the master. This greater or less aptitude to acquire perfection in muscular exercises, as well as the difference which is seen in the gait of individuals, depends, then, upon the greater or less degree in which this harmony exists between different parts of the muscular system, which derive their nervous power from the brain.

[To be continued.]

STATISTICAL ACCOUNT
OF THE
AMPUTATIONS PERFORMED AT
THE NORTHERN HOSPITAL,
LIVERPOOL,

From March 1834 to March 1841.

To the Editor of the Medical Gazette.

SIR,
SHOULD the following statistical account of the amputations performed at the Northern Hospital, Liverpool, from March 1834 to March 1841, be deemed of sufficient interest to merit a place in your valuable and highly useful journal, I shall feel obliged by its insertion. I regret that the records of the hospital do not enable me to give more ample details, with the post-mortem appearances of the unsuccessful cases; but as it is, it may perhaps be not unacceptable to some of your readers. Though containing comparatively few cases, it may yet,

if taken with others of a similar description, lead to some useful results, more especially the formation of an accurate estimate of the mortality in amputations of the extremities; and it is only in the hope that it may assist in doing so, that I am induced to lay it before the profession. I may here briefly mention that the circular operation was performed in nearly all the cases, and an attempt made to procure union by the first intention, which very frequently succeeded, if not completely, at least in great measure. The dressings generally consisted of slips of adhesive plaster, by which the lips of the wound were kept in apposition, over these lint spread with simple cerate, and the whole supported by a bandage: occasionally, instead of the lint and ointment, water dressing was applied. Ligatures of common stay silk were used, one end being cut away. They generally became detached from the tenth to the fourteenth day; but in one remarkable instance one of them remained attached seven weeks, causing no other inconvenience than a slight suppuration along its track.

Statistical account of seventy-five cases of amputation, performed on seventy-three patients at the Northern Hospital, Liver-

| | |
|---------------------------------------------------------------------------|----------|
| 20 were under 20 years of age, of which number 18 were cured, and 2 died. | |
| 15 were between 20 and 30 | 12 |
| 13 - - 30 and 40 | 8 |
| 10 - - 40 and 50 | 7 |
| 12 - - 50 and 60 | 5 |
| 1 - - 60 and 70 | 1 |
| <hr/> 71 | <hr/> 51 |
| | 20 |

Of two of the patients the age is not mentioned.

From a consideration of the foregoing tables, I think the following conclusions may be drawn:—

1st. That amputation is a more dangerous operation than is generally supposed, the proportion of fatal cases being 1 in $3\frac{13}{20}$.

2d. That it is more successful when performed for diseases than for accidents.

3d. That secondary is very much more fatal than primary amputation.

4th. That amputation of the lower is more fatal than of the upper extremity.

5th. That the danger increases with the age of the patient.

On comparing the results afforded by the preceding tables, with those of the Massachusetts and Pennsylvania Hospitals (to which, as noticed in the British

pool, from March 1834 to March 1841.—
See pp. 271, 272.

Total number of amputations 75 on 73 patients: of these 53 were cured, 20 died; being 1 in $3\frac{13}{20}$.

49 were accidents, of which 14 died, being 1 in $3\frac{1}{2}$; 24 were diseases, of which 6 died, being 1 in 4.

Of the accidents, 40 were primary (performed within 24 hours), of which 8 died, being 1 in 5; 9 were secondary, of which 6 died, being 2 in 3.

Of the primary amputations, 29 were on the lower extremity, of which 6 died, being 1 in $4\frac{8}{10}$; 11 were on the upper extremity, of which 2 died, being 1 in $5\frac{1}{2}$.

Of the secondary amputations, 7 were on the lower extremity, of which 4 died; 2 were on the upper, both of which died.

Of the amputations for diseases, 21 were of the lower extremity, of which 5 died, being 1 in $4\frac{1}{2}$; 3 were of the upper extremity, of which 1 died.

Of the whole number of amputations, 57 were on the lower extremity, of which 15 died, being 1 in $3\frac{8}{10}$; 16 were on the upper extremity, of which 5 died, being 1 in $3\frac{1}{2}$.

Below knee.—28 for accidents, of which 8 died; 9 for diseases, of which 3 died.

Above knee.—8 for accidents, of which 2 died; 12 for diseases, of which 2 died.

Below elbow.—9 for accidents, of which 3 died.

Above elbow.—4 for accidents, of which 1 died; 3 for diseases, of which 1 died.

and Foreign Medical Review, I am indebted for much valuable assistance), it will be immediately seen how strikingly they agree in leading to the same conclusions, though there are one or two minor particulars, in which some difference exists. In the cases here mentioned amputation above seems to have been more successful than below the knee, and operations on the upper extremity more fatal than in the reports alluded to; but the total number of such cases given here is so small, that it cannot in any degree be said to invalidate the common, and what I conceive to be the correct opinion.

I am, sir,

Your obedient servant,

EDWARD PARKER, M.R.C.S.E.

Assistant House-Surgeon to the Hospital.

Liverpool, April 19, 1841.

REMARKS.

^a An attack of phlegmonous erysipelas supervened, but he was discharged cured at the end of two months from admission.

^b The hand was removed at the wrist-joint. It was a very considerable time in healing.

^c Amputation was performed below the knee. The stump had nearly healed, when, two months after the operation, he died suddenly of hæmoptysis, from pulmonary apoplexy.

^d In this case one of the ligatures remained for seven weeks, causing only very slight suppuration along its track.

^e In this case there was also a dislocation of the hip, and fracture of the fibula. He went on well for three or four days, when hiccup and vomiting commenced, which increasing, soon produced an alarming state of prostration, terminating in death. On dissection, the viscera of abdomen were perfectly healthy.

^f Amputation was performed nineteen days after the injury.

^g One was amputated the same day, the other next morning.

^h Amputated three days after the accident.

ⁱ There was also a compound fracture of the right leg, which was cured.

^j On dissection, the psoas and iliacus muscles of the same side were softened and decomposed, evidently from previous disease.

^k In this case the arm was amputated at the shoulder.

"TRANCE"—PSORIASIS.

To the Editor of the Medical Gazette.

SIR,

I BEG to transmit for insertion in your journal the following account of a remarkable case of trance, which lately came under my observation. I have also subjoined a notice of a peculiar form of psoriasis, which I believe to be a novel species of that disease.

I have the honour to be, sir,

Your obedient servant,

J. M. WINN, M.D.

Truro, April 23, 1841.

On the 17th December, 1840, I was requested to see, in consultation with Mr. Pearce, of St. Austell, a young lady of that town, aged 18, who had been ailing for eighteen months with anemia, disordered bowels, and irregular menstruation. I found her suffering from amenorrhœa of two months' duration, increased action of the heart, with bellows murmur, and a congested state of the left lung; her face was pallid, and her legs slightly œdematous. I was informed that she had been affected with chorea when 13 years of age, but that the complaint subsided on the first appearance of the catamenia. I was also informed that her spirits had always been remarkably good, and that she had never suffered from hysteria. She had been under Dr. Hope's care when in London during the summer, and had taken steel, by his direction, with some benefit; she had also lately resumed the use of iron by Mr. Pearce's advice. We mutually advised the application of a blister to the side, and some draughts, composed of digitalis and a saline aperient. The steel had been discontinued previous to my arrival.

Dec. 10th.—I was informed that she was considerably better on the 9th, but that to-day she was seized, immediately after vomiting some undigested food, with profound coma. She is now lying in a comatose state. When roused she appears to be partly conscious, though speechless, and quickly relapses into an apparently sound sleep. The pupils are sluggish, and the heart beats strongly. With a view of rousing the nervous system, and of remov-

ing effusion, should any exist, we deemed it right to order turpentine injections, and blisters to the legs.

13th.—There has been little change in the symptoms. The bowels and kidneys have acted freely. The heart's action is less strong, and the bellows murmur is considerably diminished. The lungs appear to be entirely free from congestion. In consequence of the debility, ammonia and small quantities of wine were ordered.

15th.—She rallied after taking the stimulus, and opened her eyes and smiled, but speedily relapsed into a lethargic state. She takes small quantities of beef-tea and jelly at frequent intervals. Her deglutition remains unimpaired; she will, however, frequently reject the food from her mouth.

18th.—Remains in a trance-like state. She frequently opens her eyes, and smiles vacantly, but never speaks. The same remedies were continued.

24th.—In consequence of the symptoms remaining unaltered, large doses of musk, and ammoniated tincture of valerian, were ordered, in addition to the turpentine enemata.

26th.—Appeared to gain strength immediately after taking the musk, and smiled when her mother spoke.

30th.—Is evidently worse. The body is greatly emaciated; quite unconscious even when roused; moans frequently, as if in pain, and has a distressing cough; refuses at times to swallow.

Jan. 2d.—Seized at 9 A.M. with a tremor of the whole body, resembling paralysis agitans: the shaking lasted ten minutes.

To take thirty drops of the Sesquichloride of Iron twice daily, and repeat the Turpentine injections.

8th.—To-day the catamenia, of a natural colour, reappeared, and she seems to be stronger. At one period of the day she laughed loudly; she has also taken more nourishment. These circumstances have raised the hopes of all her friends. In consequence of a letter which I received from Dr. Hope, with whom I had recently corresponded respecting the case, we ordered, by his suggestion, that the turpentine injection should be doubled in strength, and that the steel should be continued.

19th.—Since the 8th she has been again declining. The breathing is

hurried, the cough distressing, and the pulse at times scarcely perceptible.

21st.—The point of the nose has become purple from extravasated blood; there is a similar effusion under the cuticle of the nates. Breathing excessively fast; is evidently sinking.

22d.—Died at three p.m.

Throughout the course of this singular case it was considered expedient to have an attendant constantly by the bed-side, to administer nourishment in small quantities; and there can be no doubt but that life was prolonged by so doing. From the commencement of the attack to the day of her death, a period of six weeks, she never spoke; and although she occasionally smiled and opened her eyes, it is probable that she never recovered, even for a moment, complete power of consciousness and volition. It is remarkable, that although the complaint was so clearly a disease of innervation, yet the digestive organs performed their functions tolerably well during the period that the trance-like condition lasted.

In Dr. Elliotson's *Practice of Medicine*, two cases of a similar kind are mentioned, both of which terminated fatally. These cases will teach the necessity of giving a guarded prognosis in severe forms of hysteria.

Three weeks since, Mr. Paull, of this town, obligingly requested a patient of his to call upon me, who had been affected for five months with a peculiar complaint of the skin. The patient, a girl *ætat.* 14, was a field labourer, and appeared to be in good health. The catamenia had not yet appeared, and she complained of headache. The eruption was confined to the right fore-arm, the left cheek, and the skin around the orbits. The patches of eruption on the arm had a singularly symmetrical appearance, being composed of concentric rings. The lines forming the different rings were even, rather elevated, of a red colour, slightly fissured, and covered with thin scales. She stated that the patches commenced with a small red spot, which soon became surrounded with a ring; that another quickly ensued, and so on in regular rotation until the patches had acquired their present dimensions. The largest patch is about four inches in diameter, and perfectly circular. She says the eruption has never been

attended with smarting, itching, or discharge. We prescribed a purgative plan of treatment, with calomel ointment; and at the end of a fortnight, when the girl called on me again, the eruption was nearly healed. I was almost sorry to find the remedies had taken effect so speedily, as it was my intention to have procured a drawing of the disease at her next visit, that I might have had the pleasure of sending a sketch of the complaint to the *MEDICAL GAZETTE*. Neither Mr. Paull nor myself had ever seen or read of a similar disease; we, however, both consider it to be a novel form of psoriasis.

DESCRIPTION OF MR. LUKE'S ELEVATING BEDSTEAD.

To the Editor of the Medical Gazette.

SIR,

EVERY surgeon in extensive practice has probably at some time or other experienced a wish to secure to his patient a ready means of elevation in bed without disturbance, not only from the convenience which results from such elevation, but also from the more speedy recovery and diminution of danger which is oftentimes thereby promoted. To effect these desirable objects, various contrivances have been suggested; which, however, by reason of the mechanism employed, have been rendered so expensive, that their application to actual practice has not been so frequent as the indications of treatment dictate.

With the view to diminish as far as possible the pecuniary objection, yet still preserving the efficacy of the means, I was induced to have constructed, for the use of the patients of the London Hospital, an "elevating bedstead," in which are combined the advantages of simplicity and cheapness, and which experience has shewn to be both effective and easy in use, and capable of being put into operation by a single nurse of the most ordinary intelligence and strength. I have been told that, as it admits of extensive practical application, it would be useful to make its arrangements known to the public. Hoping that it will so prove, I beg to send to you a description, with a diagram annexed, and to request that

ELEVATING BED.

- A. The bed on which the mattress, &c. lies.
- B. The centre on which the strong sheet is stretched.
- C. The parallel bars.
- D. The windlass, &c.
- E. Supports for curtain rods, if required.

you will kindly afford it a place in the journal over which you preside.

The first part to be noticed is the bedstead properly so called, constructed after the common mode, with the exception that it has not any foot-piece raised upon it. Its dimensions are six feet four inches in length, and two feet nine inches in breadth, and is provided with a sacking stretched upon it in the usual way, for the support of a hair mattress, blankets, &c.

The second part is a frame corresponding to the size of the bedstead. To this frame, around all its sides, is nailed a strong narrow fillet, in which holes, at equal distances apart, are made for the purpose of lacing and stretching a sheet, similarly provided with holes at its edge at similar distances. The sheet itself is also provided with a central oval aperture, for the convenience of the occupant during evacuations.

The frame is connected with the bedstead beneath by four strong flat iron bars. Each bar is fifteen inches in length, and pierced at each end by a hole, through which it is riveted to a plate fastened by four screws at one end of the bar to the side of the bedstead, and at the other to the side of the frame. These bars are arranged two on each side of the bed, one being placed near to its head, the other near to its foot, after the manner of the bars of a parallel ruler, which, in operation, they imitate.

The force which is necessary to raise the frame is applied by means of an iron arm fitted into a square socket at the foot of the bedstead; upon which arm, at its more distant extremity, is

placed a small windlass acting upon a moveable pulley, attached by a hook to a ring on the foot of the frame, in the manner represented in the diagram.

To enable the nurse to perform various offices about the occupant during the elevation, it is necessary that provision should be made for maintaining the elevation. This is easily accomplished by holes drilled through the spindle of the windlass and collar in which the spindle revolves. By means of a pin inserted into either of these holes, the revolution of the windlass is stopped at any desired point, and a maintained elevation is the result.

It is also necessary to guard against the danger of the parallel bars being drawn beyond a line perpendicular to the bedstead during the elevation. A projecting pin should therefore be inserted into the plate above the centre upon which the bar revolves.

When occupied and not elevated, the whole has the appearance of a common bed, to which curtains, if desired, may be attached. The windlass, &c. at this time is removed, and the parallel bars are covered by the bed-clothes. The occupant lies upon the sheet stretched by the frame over the subjacent mattress, &c. When the elevation is desired, the arm of the windlass is placed in its socket, and the hook of the pulley is connected with the ring at the foot of the frame, and the elevation is effected by turning the handle of the windlass, and maintained by the insertion of a pin into the hole of the spindle.

When a change of sheet is necessary, it may be accomplished without

disturbance to the occupant, by placing the clean sheet, during the elevation, upon the mattress, &c. taking care that the central aperture be in the right situation, so as to correspond to the aperture of the soiled sheet when it is allowed to descend upon it. After this descent, the soiled sheet may be detached from the frame, and the clean sheet attached in its place. The former may now be carefully withdrawn from under the occupant with little or no disturbance to him.

A bed chair, if desired, may be easily added to the head of the frame.

I am, sir,

Your obedient servant,

J. LUKE.

39, Broad Street Buildings,
April 28, 1841.

ANALYSES AND NOTICE OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

The Principles and Practice of Obstetric Medicine and Surgery, in reference to the Process of Parturition. With 100 Illustrations on Steel and Wood. By F. H. RAMSBOTHAM, M.D. &c. &c. London, Churchill. 1841. 8vo. pp. 672.

THE notice which we have already taken of the first part of this work, when it was in the progress of publication, is much too brief to do justice either to the author or his very spirited publisher. It is intended expressly for students and junior practitioners in midwifery. It is, therefore, as it ought to be, elementary, and will not, consequently, admit of an elaborate and extended review. Our chief object now is to state our decided opinion, that this work is by far the best that has appeared in this country, for those who seek practical information upon midwifery, conveyed in a clear and concise style. The value of the work, too, is strongly enhanced by the numerous and beautiful drawings, by Bagg, which are in the first style of excellence. Every point of practical importance is illustrated, that requires the aid of the engraver to fix it upon the mind, and to render it clear to the comprehension of the student. We shall offer a few comments upon some points of prac-

tical importance that have attracted our attention in perusing the work.

Dr. Ramsbotham observes, upon the subject of lingering labour, from ovarian tumors in the pelvis, that “we may establish the principle, that if the swelling possess the least degree of fluctuation evident, a puncture should be made into its substance, by means of a trochar introduced through the vagina or rectum.” Mr. Ingleby* has published several interesting cases which bear upon this point, and which would induce us to puncture an ovarian tumor, which impeded the passage of the child through the pelvis, even if there were *not* “the least degree of fluctuation” to be detected. For, if the head of the fœtus is powerfully pressed upon a tumor that does contain fluid, and which might be evacuated by a moderate-sized puncture, the tumor might still feel very hard and resisting, and offer to the touch no evidence of fluctuation. Mr. Ingleby, with praiseworthy candour, relates cases in which he was thus at first deceived. In one instance the tumor reduced the diameter of the pelvis to one inch and a half. The head of the child was not within reach. The tumor felt hard, like cartilage. It was not softer in one part than another. There was no fluctuation evident in it. It was not harder during the pains of labour, than in their absence. Here the difficulties were great. The tumor could not be pushed above the brim of the pelvis. Embryotomy was impracticable, and the Cæsarean section seemed the only resource. Before, however, this desperate expedient was thought of, Mr. Ingleby, as an experiment, thrust a trochar into the tumor, and drew off seven ounces of clear fluid. In another case he drew off twelve ounces of fluid from a tumor thought to be solid. And he alludes to two other cases where prolapsed ovaria, filled with pus, felt so solid, that puncturing was not thought of, and both cases terminated fatally. In short, we perfectly agree with Burnst†, that, “as it is impossible to decide with certainty on the nature or contents of many of these tumors, we ought, in all cases, where we cannot push them up, to try

* Cases in Midwifery(?). We quote this title from memory, but we made a note of the cases referred to when we read them.—*Rev.*

† Midwifery, p. 36, 8th edition.

the effect of puncturing from the vagina with a trochar."

At page 347, Dr. R. refers to Dr. D. Davis's "Osteotomist," an instrument which "is intended to break up the bones of the child's head, particularly at the base of the skull, so as to enable the operator to extract the fetus through a very narrow pelvis, and to prevent, in many instances, the necessity of having recourse to the Cæsarean section." We should wish to know whether this instrument has ever been used in practice; and we would just observe, that it may be very easy to "make large breaches in strong ribs of beef" by the osteotomist, but neither easy nor safe to employ it on a living woman. Our own experience as to the alleged power of the ergot of rye, in inducing uterine action, would lead us to agree with Mme. La Chapelle, "*que son innocuité est sa plus grande vertu*." We willingly quote the better, because affirmative, evidence of Dr. Ramsbotham. He states that, in cases in which he wished to induce premature labour, he "made some experiments with the ergot, and that he found expulsive action soon follow its exhibition in all instances, with very few exceptions, when he administered it."

Notwithstanding the complete failure of the ergot in about forty cases in which we have given it, we would still have recourse to it under appropriate indications, from the confidence with which many respectable authorities speak of its power.

Transverse presentations.—We do not perceive that Dr. R. adverts to the occasional possibility, when the hand or shoulder presents, of avoiding the operation of turning, by adopting the practice mentioned by Gooch and others, and which, in three or four instances, we have had recourse to with success. Gooch says†, "Sometimes, when the hand or shoulder presents, the head rests on the edge of the brim of the pelvis, and if you return the presenting part, the uterus is so stimulated to a vigorous action, by the introduction of the hand, that the head is thrown off the brim of the pelvis, and descends as in a natural presentation. I have succeeded in this way in many cases; and in some, to which I was called for the

express purpose of turning, while apparently only making a common examination, I have returned the presenting part, and then waited for a pain, which has brought down the head." This is a very different mode of practice from the old and now abandoned attempt of grasping the head, after pushing back the shoulder, so as to bring the vertex over the centre of the superior aperture.

Uterine hæmorrhage.—Dr. R., we apprehend, is much more fearful of blood collecting in the gravid uterus, so as to endanger or even destroy life, when its external escape is prevented by plugging the vagina, than the records of obstetrical experience will justify. As far as we know, this apprehension has been more frequently fancied than proved: for cases in point are rare, and even the possibility of such an occurrence has been doubted by many high practical authorities, some of whom are quoted by Dr. R. To the names he mentions we would add, the always valuable evidence of Madame La Chapelle, whose long experience confirmed her both in the safety and efficacy of the plug*. This subject is of importance. Our means of arresting uterine hæmorrhage, in cases where we cannot deliver the patient with safety, are few. Plugging the vagina, we, in common with many of the best practical authorities, regard as one of the most valuable in certain cases, and we may fairly require very good evidence, before we allow our confidence in the practice to be diminished. We are, of course, referring to the use of the plug in the latter months of pregnancy. Its safety, and certainty, in the early months, is not disputed. Dr. R. tells us, in a footnote, at page 504, that "more than one instance has come within his knowledge" of internal hæmorrhage occurring in the gravid uterus. Now granting this fact, and we do so willingly upon the assertion of the author, we would reply, that plugging the vagina is not to be slightly thought of in appropriate cases, because in the course of extensive practice "more than one instance" has proved its occasional failure, any more than we should be justified in abandoning the

* Davis's Obstetric Medicine, vol. ii. p. 1164.

† Accouchemens, t. i. p. 52.

‡ Midwifery, by Skinner, p. 236.

* Pratique des Accouchemens, par Dugès, t. ii. 352.

practice of rupturing the membranes, for the purpose of arresting uterine hæmorrhage, because it also is not invariably successful.

We are not at all inclined to deny the truth of Dr. R.'s assertion, that, in cases of placental presentation, "in the great majority of instances, the patient will die if relief be not afforded; and that, under entire placental presentations, delivery should be effected by art as early as is practicable, without incurring the risk of injury." We merely touch upon this subject for the purpose of stating briefly the practice recommended by Wigand*. As far as we know, the opinions of this celebrated writer upon this important practical point have not before been given to English readers. In placental presentations, with slight hæmorrhage, he keeps the patient as quiet as possible both in mind and body. During the intervals of the hæmorrhage he allows her to move about gently, but carefully to avoid fatigue. The bowels are kept open once daily. Excepting occasional aperients, no other internal medicines are given, except in particular cases. Upon the first occurrence of true labour-pains, or rather free hæmorrhage at about the period of labour, he plugs the vagina with soft linen, steeped in thick gruel; the upper part of the plug being moistened with a solution of gum Arabic and powdered resin. He introduces the plug high enough to enter the os uteri, and to lay firmly against the separated edge of the placenta. And, in order that the plug may remain firmly and immovably in this position, he further fills the vagina, in every direction, as completely as the patient can bear without pain, with linen or pieces of sponge. He then lays a thick dry towel externally and firmly upon the os externum. He takes care, at the same time, to remove any morbid condition of the uterus that may happen to exist, "as rheumatism, spasm, or inflammation." The disposition to bear down, which will sooner or later arise from the artificial distension of the vagina, must be supported as long as possible by the patient. If she succeeds in conquering this disposition for about half an hour, the vagina becomes accustomed to the irritation, and remains quiet. If, in a few hours,

the pains becoming more rapid and stronger, the bearing down sensation is accompanied by a burning feel in the vagina, the original plug is replaced by a smaller one. Before this smaller plug is applied, an examination is made per vaginam, and the following circumstances are especially attended to. Whether the os uteri is much expanded, and whether the placenta has already begun to separate from one or the other side. Whether the head, or the feet, or what part of the child presents. Whether the bladder of membranes is distended. And whether it can be ascertained that both the presenting part of the child, as well as the separated edge of the placenta, are equally and simultaneously pressed down during the pain. If any other part than the head, feet, or breech, presents, Wigand turns as soon as he can; but if the presentation is natural, the pains powerful and frequent, the passage of the child quick, and if the patient's pulse is full and slow, he leaves the delivery entirely to nature. In the course of some time unusually quick and powerful pains come on, and expel the child "alive and merry" (*lebendigen und ganz munteren Kinde*), together with the tampon. The placenta is expelled spontaneously; and soon after the child, when this practice is adopted. Wigand assures us that for many years he has carried this practice into effect in cases of placenta prævia, and that he has not lost a single woman or child; and that the recovery of the patient has always been favourable. He admits that there are cases in which this plan would not be applicable. For example, in women with such irritable vaginae that the plug could not be borne; or if the hæmorrhage had greatly exhausted the patient before the practitioner was consulted.

Dr. Ramsbotham comments very properly upon the hazardous remarks of some writers, whose statements may lead young practitioners to the belief that, in cases of retained placenta, from morbid adhesion to the uterus, it not unfrequently happens that it is inevitably necessary to leave a portion of the placenta in the uterus. "It would be my wish, on the contrary, to inculcate the idea that the *whole* can very generally, and ought, even at the expense of some trouble, to be removed; and that we should never feel satisfied

* Geburt des Menschen, p. 132. Berlin, 1839.

that we have done our duty, unless we have used our best endeavours to effect its entire abstraction." Our "best endeavours" must of course be compatible with the safety of the patient, and how far we may endeavour to remove the whole of a morbidly adherent placenta must be left to the judgment of the practitioner in each individual case. "If," says Burns*, "the adhesion of part of the placenta be very intimate, we must not, in order to destroy it, scrape and irritate the surface of the uterus; but we ought, rather, to remove all that does not adhere intimately, leaving the rest to be separated by nature." In several instances that have occurred to us we have been compelled to leave a large portion of the placenta in the uterus, as a lesser evil than that of using great force to separate its close adhesions. We perfectly agree with Dr. R. that such an alternative is a fearful one; but we are sometimes compelled to choose it; and in the cases we refer to we have done so with safety, for the retained portions have been expelled without severe hæmorrhage or serious symptoms afterwards.

Inversion of the uterus.—Dr. R. states that unless the uterus be replaced "within a short time when the accident took place, he should presume either that the uterus could not be reduced at all, or that the hæmorrhage must be excessive."

We would just observe that spontaneous reduction has been known to take place when the inversion has been of long-standing†. Gardien‡, again, an excellent practical authority, says, "Les auteurs n'ont tant insisté sur la nécessité de réduire sur-le-champ la matrice, que parcequ'ils étaient dans l'opinion que si on laissait échapper ce moment, on rencontrerait par la suite plus de difficulté, qu'elle deviendrait même impossible. L'expérience apprend, au contraire, que la réduction est quelquefois plus facile au bout de plusieurs jours qu'après quelques heures de retard seulement." We have recorded a case of Dr. Belcombe's§, in which the inverted uterus was replaced

twelve weeks after its displacement; and in twenty days the patient was well enough to travel. The hæmorrhage had been severe during the whole time the uterus was inverted. Dr. R. would prefer returning the inverted uterus and placenta together, and afterwards removing the placenta from the uterus; while others recommend that the placenta should be separated from its attachment before any attempt is made to replace the uterus. Barlow's observations upon this subject are worth noticing. He says*, "The mode of replacing the inversion, as usually recommended by authors when the placenta is adherent to the inverted uterus, is to return both organs at the same time, without first separating the one from the other. This counsel, though resting on high authority, should be received and acted upon with great caution, as the bulk of the two protruded organs, when surcharged with blood, will present such resistance to the exertions of the accoucheur in attempting reduction under these circumstances, that it cannot be effected without using great violence, and exposing the woman to imminent and unnecessary danger; and supposing it to be accomplished in this way, the placenta will have to be disparted in the uterus, and afterwards extracted, and great risk incurred of a second inversion, which presents a material objection to this mode of proceeding. The more rational and less injurious method appears to be in all cases, whether the placenta be attached to the uterus, or otherwise, to compress the whole substance between the hands like a sponge, by which the blood will escape, and the uterus be diminished in size; and the placenta, if adherent at the same time, will be separated, so that its reduction may be safely and easily accomplished without further interference."

Hæmorrhage after the removal of the placenta.—Dr. Ramsbotham very wisely deprecates the advice that is given by many authorities, of *immediately* introducing the hand into the uterus, in cases of severe hæmorrhage after labour. He would first adopt the less harsh and safer means of external pressure, and the application of cold to

the uterus. If these means fail, which we know they will not in the majority of cases, the hand must then be introduced into the uterus to remove any coagula it may contain, and to ensure efficient contraction. We very cordially agree too with Dr. R. upon the much disputed point of the use of opium in severe cases of uterine hamorrhage, although his opinions are opposed by the high names of Burns, Stewart, &c. "I have stated that opium, in large doses, is very much extolled in cases of flooding, especially by Professor Burns and Dr. Stewart, but that I consider it a medicine inadmissible, unless the uterus have entirely contracted, and when the danger of fresh bleeding has gone by. Opium certainly acts as a cordial, lulling the irritability of the patient, and producing sleep, or, at any rate, a composing stupor; but it also takes off both muscular and uterine action: it disables the uterus, therefore, from contracting, even when it is so disposed: and if the proposition be true, that on the contraction of the uterus alone we are to rely for the patient's ultimate safety, it cannot but appear contradictory to resort to a medicine whose very action tends to prevent the effect desired. It has been objected, that although opium, in small quantities, takes away uterine action, yet, in large doses, it produces the very opposite result, and excites contraction. This proposition is at variance with common sense, with all analogy of the actions of other drugs, and at least with my experience. I have often seen, at the commencement of labour, uterine action suspended by what would be considered a large dose of opium: and if the same quantity will take away action at the beginning of the process, is it reasonable to suppose it will excite it at the termination? But it may be said the experience of practitioners of eminence proves the value of opium in the case under consideration, and that there is no reasoning against experience. I by no means deny that many patients have done well after the administration of large doses of opium; but that circumstance does not prove that the drug was the agent of their preservation. I should be inclined to attribute the recovery to other causes, independently of the exhibition of the medicine. I strongly recommend opium in large doses, and the solid form in those

cases of irritability produced by a loss of blood which had previously taken place; but that only when the uterus is contracted, and the danger from flooding is past," p. 551.

Once more we strongly recommend this work to the student who wishes to become acquainted with all the leading doctrines and facts of obstetrical science, as a sure and safe introduction to the perusal of more elaborate works.

Researches on Operative Midwifery, &c. With Plates. By FLEETWOOD CHURCHILL, M.D. &c. &c. Dublin and London, 1841. Svo. pp. 360.

THE greater part of this work has already appeared in different periodicals in the form of detached papers; and, with every disposition to applaud the industry of the author, we cannot refrain from saying, that no additions are made to the volume before us of sufficient importance to justify their republication. The "table of contents" comprises accounts of the artificial induction of premature labour; of version, or turning; of the vectis, or lever; of the forceps; of the perforator and crotchet; of the Cæsarean section; of symphyseotomy; of the umbilical cord; a report of the Western Lying-in Hospital; and lastly, a chronological catalogue of midwifery authors. It has always been our opinion, that the merit of a good practical compilation, and the requisite ability on the part of the compiler, are generally very much underrated; and we are not at all inclined to doubt, that Dr. Churchill has enough of literary knowledge, and quite sufficient practical judgment and experience, to enable him to give a good and very acceptable abstract of the opinions of foreign and English writers, as well as of the standard practice of the day, on obstetrical subjects. But neither of these objects appear to us to be satisfactorily effected by these "Researches." They consist chiefly of a chronological history of obstetrical operations, to which follows, for the most part, a very meagre account of the practice now generally adopted. Some of the statistical records and tables are valuable. The essay on the funis umbilicalis, and the report of the Western Lying-in Hospital of Dublin, give the volume a respectable appearance as to its bulk,

but any great merit these additions contain has escaped us; although, in justice both to our author and our readers, we perused them with becoming attention.

MEDICAL GAZETTE.

CICERO.

'PRACTICAL REMARKS' ON REFORM.

AFTER many nibbles, you may expect a bite, say fishermen; and after the several crude schemes, and bills not to be passed, which medical reform has inflicted on us, it is probable that something efficient will really be done, although we doubt whether it will now be accomplished during the present session. If we were to hazard a conjecture concerning the nature of the alterations likely to take place, we should predict that they would be of two kinds. In the first place, several medical corporations will be compelled (for better or for worse) to throw down the wall which separates their esoteric from their exoteric members, and thus admit all alike into the interior of the temple. Secondly, some changes will be made in the system of medical education. On both these subjects the greatest difference of opinion naturally prevails; and it is scarcely possible that the details of any new regulations should be generally acceptable, even in theory; far less in their practical working. Meantime, the continual discussions of delegates, the declarations of councils, and the ceaseless torrent of articles and pamphlets, show that the profession expects its deep-seated evils to be speedily taken into consideration by Parliament. Men of name, and men of no name, have alike

spent their money in paper and print, and, disdaining to give a silent vote, have set forth at length the reasons which induce them either to acquiesce in the present system, or else to hope for better things from a regenerated profession. Among the throng comes a general practitioner of no very decided opinions*, but who probably represents the doubts and hesitations of a considerable class. He desires, he says, "to tread in the straightforward path of truth and honesty, and to rank with those who form an exception to the general rule; but who, fearlessly as they give their opinions, forget not that low and vulgar satire is not reason, and that falsehood and abuse are not substantial and conclusive arguments."

Quid dignum tanto feret hic promissor hiatu?

On the first of the two kinds of reform which we alluded to above, the General Practitioner says but little. He merely suggests that some of the licentiates of the Apothecaries' Company might be elected into the Court of Examiners—a distinction now confined to Members. On the other point, or medical education, he says more, but nothing which is very striking. In examinations he would "cautiously steer between the two extremes, believing the middle path to be the safest." No doubt; so would we all. But the questions remain, where are the two extremes, and which is the middle path? For instance, to take a topic discussed by the author—should a competent knowledge of the classics be required from medical students, or not? At present, the quantum demanded at Apothecaries' Hall is too trifling to deserve mention; and though the number of candidates plucked in this sub-

* Practical Remarks on the measures proposed for reform in the medical profession. By a General Practitioner, &c. London, 1841.

ject is considerable, this is a proof rather of the inefficiency of our common schools, than of the severity of the examination.

The Quarterly Review, on whose opinions we commented some weeks ago, observed that the preliminary education of students was quite overlooked both by the College of Surgeons and the Society of Apothecaries, except that the latter required the candidates to construe some scraps of Latin. The General Practitioner cannot understand what is meant by "scraps of Latin," and seems somewhat scandalized at the phrase. If he lives in some *pays Latin*, where every one is up to the mark, has a scholarlike acquaintance with the language, and repudiates fragmentary knowledge, we would recommend him to visit the establishment of a London grinder, or examine a few pupils going up to Blackfriars: and if that does not teach him what "scraps of Latin" means, his case is hopeless. He fears something, moreover, which is not likely to be proposed by any one. He dreads some romantic attempt to extend the usefulness of practitioners by "high classical requisitions." But let him dismiss his fears: no one proposes that the mass should do more than come up to a low standard in classics; a high one is quite out of the question. The "General Practitioner" makes a curious objection to the statement of the Quarterly Reviewer, when he thinks that the latter must have overlooked the recommendations of the Court of Examiners; for they assert that a familiar acquaintance with the Latin language is indispensable, and a knowledge of Greek scarcely less so. The difference between preaching and practice was never more clearly exemplified: the pamphleteer quotes the former, and the reviewer the latter. If all these recommendations of the Worshipful Society were

followed, the young practitioner, with his store of Greek and Latin, French, German, and mathematics, together with medicine and its ancillary sciences, would be a very remarkable person; one whose attainments must be the subject of universal envy, and whose education the most zealous reformer would scarcely venture to meddle with.

But since the facts are otherwise, let us consider why some candid persons wish for a reform in this particular, and desire the practice to be brought up to the preaching. The "General Practitioner" observes that members of our profession may be extensively useful with a comparatively scanty measure of classical knowledge. This is true; they may be useful, not only with a comparatively scanty measure, but with no measure at all: a practitioner may treat fever very sensibly, though he could not read what Celsus says on the subject, were it to save his own life, instead of the patient's. Nay, we may go much farther; a man may obtain a large practice, though ignorant of the elements of literature; and many a surgeon may cure a broken head with great skill, though in the constant habit of breaking Priscian's. Ancient and modern languages, the exact sciences, chemistry and botany, nay anatomy itself, have sometimes been thrown overboard, and the vessel has seemed to sail the better for losing its cargo. But this spoliation of the stores of the mind is a dangerous experiment. Martinus Scriblerus endeavoured to give his son an abstract idea of a Lord Mayor, without a great horse, without a gold chain, without custard; and thus some theorists, with the hope of retaining the essential, and the essential alone, would reject the greater part of what have always been considered the ornamental necessities of a professional man.

But while the partisans of a minimum of education may quote some strong examples in favour of their arguments, those who recommend a larger acquisition of knowledge do not lack topics to urge on their side of the question. They allege that although instances are not wanting of practitioners who have attained great success, with an imperfect education, and uncultivated mind, yet that such examples are rarer than is sometimes asserted; that, on the whole, he who has most tickets has the best chance in the lottery of life; and that the social superiority of a professional man to the most ingenious artisan, depends, in a great measure, on his general information. They add, that the position of a whole profession in society is to be estimated not by the reception given to a few of its leaders, but by the place vouchsafed to a mere average member; and that if we adopt this reasonable criterion, much remains to be done to elevate the practitioner of physic. In conclusion they observe that we may apply to the practitioner of physic what was said of lawyers by a great authority, that every kind of knowledge comes into play in the practice of his profession. Hence we may learn, in answer to the General Practitioner, why so sound a critic as the Quarterly Reviewer desired the standard of classical knowledge to be raised among students; not merely that they might know the names of the tools they use, and read some great writers in the original languages, but that they might enlarge their minds by the conquest of difficulties, and contend on equal terms with the other learned professions.

The same considerations, *mutatis mutandis*, may be applied to the other branches of study recommended by the Worshipful Society.

Still the education of a numerous body cannot be radically amended in a moment. In order that these preliminary studies may be pursued with advantage, our common schools must be improved; or parents must be warned against those ill-managed academies, where nothing is tolerable but the prospectus. However, just as we urged in our late observations on Dr. Peacock's proposed reforms, that the improvements made at Cambridge will necessarily benefit the schools which prepare students for the University; so it is in the power of the Society of Apothecaries to effect improvements in many schools by demanding something in the shape of a preliminary education.

Such an examination would, of course, be sufficiently easy to allow students, even from our common schools, to pass without much difficulty; for any barrier suddenly checking admission into our ranks, and excluding a host of applicants, would be considered, and with justice, a practical grievance.

The same may be said of examinations undergone by the pupil after the completion of his professional studies, but with an additional circumstance. If any thing is added to the length or severity of the present studies, it should be in purely practical matters; and it might be well to make room for the essential, either by dispensing entirely with some of the minor subjects, or by confining them within narrow limits. The medical colleges, which we suggested in our article of April 2d, would be admirable adjuncts to any improvements in professional education, giving life and existence to regulations which, for want of them, are too often but a dead letter. Mr. Green, in his late pamphlet, "The Touchstone of Medical

Reform," suggests that candidates for general practice should be examined by the Colleges of Physicians and Surgeons; as an examining Board, consisting of general practitioners, would be likely to alienate them from those bodies, the character of which tends to give them rank and estimation. The author of the pamphlet, on the other hand, thinks that the rise of general practitioners in the profession is chiefly attributable to the regulations of the Society of Apothecaries; and he consequently wishes still to leave in their hands the office which they have discharged so well. The objection founded on the connection of general practitioners with trade, he thinks the offspring of mere ignorance.

"Very many of the general practitioners of London confine their demands upon their patients to medical or surgical attendance; and where this is not strictly the case, in the majority of instances it is owing to the public mind not being alive to the importance of such a procedure, and not a voluntary act on the part of the practitioner himself."

This statement is obviously an exaggeration; for as the middle classes insist on having physic as well as advice from their medical attendants, the man who endeavours to obtain practice among them must per force comply with their wishes.

What was the origin of the Apothecaries' Act in 1815? The General Practitioner says it was the result of an inquiry into the state of four districts in the North of England, where the regular doctors were far outnumbered by the unlicensed ones. According to Gray*, the immediate origin of the Act was a meeting convened in July 1812, to consider the high price of glass.

* Supplement to the Pharmacop. pref. p. xix.

LONDON UNIVERSITY EXAMINERS.

WE are quite at a loss to understand the principle on which the office-bearers of the London University are elected. Last year Dr. Tweedie was set aside, without any one knowing why, and Dr. Watson elected in his place. This year the former is replaced again, and the latter discharged, quite as unexpectedly as in the former case! The impression naturally produced under ordinary circumstances would be, that the party set aside had, in some way or other, been found unfit: but the chopping and changing which this season has produced, shews that some other and totally different considerations have been at work.

Among those elected examiners on the 8th of last month was Dr. Ferguson, of King's College; but he, staggered by the omission of Dr. Watson's name from the list, has tendered his resignation, as appears by the following letter.

"9, Queen Street, May Fair, 16th April, 1841.

MY LORD,—As President of the Senate of the University of London, permit me to tender to your Lordship my resignation of the office of Examiner in Midwifery, to which I had the honour of being appointed on the 8th instant.

The fact made apparent at the late election, that a faithful and efficient discharge of the duties of an office may nevertheless be followed by dismissal, has compelled me to withdraw myself from a position which, though honourable in itself, may entail on me also the implied censure of a rejection.

I need not assure your Lordship, that could I have foreseen the results to which I have alluded, I should have at once declined the offer of those friends who did me the honour of requesting me to serve as an Examiner. And I have only now delayed tendering my resignation a few days that I might avoid the imputation of a hasty decision in so important a matter, or the slightest appearance of disrespect towards that body of gentlemen over whom your Lordship presides.—I am, my Lord,

Your Lordship's obedient servant,
ROBERT FERGUSON, M.D."

These occurrences will render most persons—at least those who are fit for the appointments in question—rather chary about accepting them.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

April 23, 1841.

DR. WILLIAMS in the Chair.

Observations on the Anatomy of the Lungs.

By THOMAS ADDISON, M.D., Physician to Gay's Hospital.

THE author begins by expressing an opinion, that notwithstanding the attention which has been devoted of late to morbid anatomy, it is by no means apparent that those researches have been made sufficiently available to explain the function and structure of obscure, intricate, and complicated parts of the body in a state of health. Proceeding on this principle of rendering healthy and morbid anatomy mutually subservient to the elucidation of each other, the author hopes that he has succeeded in illustrating, if not in demonstrating, certain points of great interest with reference to the lungs, some of which have been already pretty generally admitted, whilst others are perhaps altogether novel. The results of his investigations on this subject seem to him to prove almost beyond dispute—That the aerial cellular tissue of the lungs is made up of well-defined, rounded, or oval lobules, united to each other by interlobular cellular membranes, each lobule constituting a sort of distinct lung in miniature, having its own separate artery and vein; that those lobules do not communicate directly with each other; that they do not, as Reissessen has supposed, consist of the globular extremities of as many bronchial tubes, but, on the contrary, as Dr. Hodgkin has suggested, are made up of a collection of cells, in which, by a common opening, a minute filiform bronchial tube abruptly terminates; that the pulmonary artery accompanies the bronchi, branch for branch, to the minutest divisions of the latter; that pneumonia consists essentially of inflammation of the aerial cells; that pneumonia and inflammatory tubercle are identical; that acute pneumonia in healthy constitutions scarcely ever leads to the formation of an abscess, unless deposit previously existed, but that when it occurs in cachectic or broken-down constitutions, or supervenes in the progress of organic diseases, it causes one or more distinct lobules to soften down into an ill-conditioned abscess; that ordinary tubercles present the same varieties in the lungs that they do in serous membranes; that emphysema of the lungs consists chiefly of mere dilatation of the cells, but in parts also of more or less extensive laceration of them; and, lastly, that the circumscribed gangrene of Laennec is commonly, if not uniformly,

a mere effect or advanced stage of pulmonary apoplexy.

The author's object, however, in the present communication, is not to solicit attention to any of these matters, but merely to point out a mode of distribution of the pulmonary veins which has not, as far as he knows, been noticed by any preceding anatomist. After having cited passages from the works of Cloquet, Meckel, Adelon, Ollivier, and Bichat, touching the situation and course of the minute pulmonary veins, the author proceeds to shew the mode of their distribution which his own dissections appear to demonstrate. It would exceed the limits of an abstract to give the author's description at length; suffice it to say, that the lung is made up essentially of a vast expanse of membrane, the interior of which is unceasingly exposed to the influence of atmospheric air, and upon the surface, or in the substance, of which are spread out the capillary ramifications of the pulmonary artery; these arterial capillaries passing from thence to the exterior of the membrane to form the pulmonary vein, which, throughout its whole course, is found to be situated on the exterior of the aerial cellular structure of the organs. The author indulges a hope that, with a knowledge of this striking distribution of the pulmonary vein, we shall, in future, be more successful in our investigations into the pathology of phthisis; and especially that it will set at rest the long-agitated questions respecting the origin and seat of pulmonary apoplexy.

The president remarked that the paper just read appeared to him to possess peculiar interest, not merely in regard to anatomy and physiology, but still more in its relation to pathology. If he had understood its import aright, it implied that henceforward many of the diseases of the lung would be much more under control, and even that we might see no more of phthisis. He should be very glad to hear from the author somewhat more of the application of his discovery to pathology.

Mr. Bransby Cooper said he feared that the president had, like himself, been somewhat disturbed in his attention to the paper by the interruption which had accidentally arisen, and by the difficulty which the secretary had experienced in deciphering Dr. Addison's hand-writing. Mr. Cooper, then detailing what he thought he had understood to be the objects of the paper, said that he believed it would be found to have peculiar interest, especially by the relation which the lungs were now found to hold with certain other organs of the body, in regard to the distribution of their vessels, and the separated course of their arteries and veins. In the thymus and thyroid glands, for example,

and in the capsulae renales, there was a similar separation of the arteries and veins, only in these the arteries were on the exterior, the veins in the interior of the organs; while in the lungs Dr. Addison had shewn the arteries in the interior, the veins in the exterior of the organ; for of course the exterior of the lobules on which these veins were traced might be spoken of as the exterior of the organ. He thought it likely that this difference of relative position might have something to do with the very different offices of the veins in the two cases; which were, in the one, to carry purified blood from the capillaries to the left side of the heart; in the other, to carry deteriorated blood into the general venous system.

Dr. Addison said he did not think there was any expression in his paper that could justly lead to the idea that he contemplated, as a result of his discovery of the course of the pulmonary veins, the extinction of phthisis. At the same time he believed that it might prove of some importance in the determination of the true seat and pathology of certain pulmonary diseases. For example, it is still a question whether, in what was called *œdema pulmonum*, the serous fluid with which the lungs were found loaded was situated in the air-cells of the lungs, or in the cellular tissue investing them and the lobules; and so also in pulmonary apoplexy, it was still disputed what was the seat of the effusion of blood. Now these and many similar questions he thought might be explained by following out the mode of investigation he had adopted. If, for example, on separating the lung into its parts, lobule by lobule, as he had done, it was found that the fluid effused was not removed or diminished in quantity, then there could be little doubt that the interior and not the exterior of these parts of the organ were its true seat. And so on for several other questions; as, for example, the seat of tubercle of inflammatory tubercle, of pneumonia, &c.

Mr. James Blake said, that he could not understand from Dr. Addison's description what the means of communication between the ultimate branches of the pulmonary arteries and veins were. He had spoken of the arteries as passing to the interior of the lobules, and of the veins as arising from their exterior; but had not mentioned the means by which they were connected. It was surely not probable that they formed an exception to the general law now universally received, of arteries and veins being connected by an intermediate system of capillaries arranged in a network.

Dr. Addison said, that he imagined the pulmonary vessels did also so communicate, but still the preparations showed that the arteries passed to the interior, and the veins

came from the exterior of the lobules. In answer to a question by Mr. B. Cooper, Dr. Addison said that he supposed it was not possible to tell whether minute vessels of the lung ran on the surface or in the substance of the membrane of the aerial cells. He also detailed some observations which he had made on the distribution of the vessels in the lung of the frog, in which there was a similar separation of the main arteries and veins, only that here the pulmonary vein ran in the interior of the saccular lung, as if to guard it from pressure during any great exertion of the animal, by placing it in a medium of elastic air.

Mr. Bowman said that the microscopic examination which he had made of the structure of the lungs had shewn him that the air-cells were composed of a perfectly homogeneous tissue, and that they were all lined by a very fine epithelium, thickly set with ciliae, which were during life continually vibrating. This ciliary epithelium was the continuation of that which lined the whole of the bronchial tubes. He had no doubt that the capillaries of the lungs might be said to be arranged in the substance of the membrane of the air-cells; that is, like the capillary vessels of all similar membranes, they are placed beneath the epithelium. In a lung he had recently injected he had observed the same isolation of the pulmonary veins from the arteries and bronchial tubes as Dr. Addison had described, but at the time had thought it of no practical importance.

Mr. Paget said that he thought the misunderstanding respecting the arrangement of the arteries on the interior, and the veins on the exterior, of the structures, had arisen from its being supposed that Dr. Addison had described the vessels, not of the pulmonary lobules, but of the air-cells. In the air-cells it was quite certain there were nothing but capillaries, nor could it be possibly determined whether on them the arteries or veins were separated; for the vessels there were in fact not distinguishable as arteries and veins, but were merely an intermedium between the two. What Dr. A. had described were the coarser branches of the arteries and veins, of which it appeared that the former ran into the interior of the lobules or collections of air-cells, while the latter were arranged on their exterior. He would take the opportunity of mentioning, what might have some interest in its relation to Dr. Addison's discovery, that in the last three cases of pulmonary apoplexy that he had examined, he had found the pulmonary veins coming from the seat of the effusion completely blocked up by very firm fibrinous coagula, similar to those formed in phlebitis, and evidently formed long before death.

Dr. Addison said that his preparations

would show that he had injected not merely the larger, but the smallest branches of the pulmonary vessels; and the veins might be seen in them ramifying like the diverging fingers of the hands or claws on the exterior of the lobules. He then entered, with some detail, into the pathological deductions which he believed might be made from the fact which he had discovered; and after some observations from Dr. Mayo the Society adjourned.

THE MEDICAL SCHOOLS.

To the Editor of the Medical Gazette.

SIR,

As there are now in this metropolis so many *soi-disant* schools of medicine, and so various in the means of instruction they afford to their pupils, it is much to be lamented that some strict *surveillance* is not by law established over them. Young men raw from the country are led to enter certain schools by various motives; and as all are recognized, they feel sure they cannot err in their choice. Too late do some find they have taken a step which they will silently lament all their days. Silently, I say, because, were they to complain, such complaint would involve their own reputation. They may have *passed*, it is true, thanks to the grinders, but their conscience is not satisfied. Their time is irrevocably lost—their money is gone—they are not half educated. It would be generous in the old respectable schools to open their doors to the duped, and to allow them to finish their education at a less charge than what is demanded from the fresh pupils, which they, in many cases, could afford; but to pay all over again is more than many in our poor profession can find the means to do. Surely the College of Surgeons, who have the surgical, and of course the anatomical departments of medical instruction under their charge, should deem it a moral duty to inspect the schools, and see if the facilities for acquiring a proper knowledge of these subjects be afforded to the pupils. In many cases of rejection the censure should fall on the teacher, and not on the candidate for the diploma. It is to be feared some schools are not established for teaching, but for the purpose of getting the fees.

It may be said, these things will find their own level: no such thing. If the pupils were to pay for each course, they would find their own level; but, in such establishments, he who takes his tickets for all the prescribed courses at once, gets them at a reduced price. Once caught in the trap there is no retreat, and silence is discretion.—I am sir,

Your obedient servant,

AN OBSERVER.

GLASGOW COLLEGE.

10th March, 1841.

MEDICAL REFORM.

A MEETING of senate being duly summoned and convened, the committee appointed by the senate to consider the Bill for the better Government of the Medical Profession, which has been introduced into the House of Commons by Mr. Warburton and Mr. Hawes, beg leave to report—

1. That, in the opinion of the committee, evils have arisen from the possession by particular corporations of local privileges, which render their licentiates alone legally qualified to act as medical practitioners in particular districts of the country, to the exclusion of all other persons, however highly qualified.

2. That it is desirable that those local privileges should be abolished, and a uniform system adopted, whereby the graduates of all universities, and the licentiates of all legally constituted medical corporations, shall be placed on an equal footing, in respect to the right of practising; so that those who have received certificates of their fitness to exercise the medical profession from any one of the established corporations, shall be entitled to practise in any part of the United Kingdom, without requiring to submit to a second examination, or pay for a second license.

3. That the most essential part of such uniform system must consist in the general adoption of a certain course of education, as the *minimum*, entitling any one to become a candidate for a medical license.

4. That the measures proposed in the bill recently introduced into parliament are inadequate to the accomplishment of the objects in view, and could not be carried into effect, without the most serious inconveniences.

5. That neither the proposed compulsory registration of licensed and qualified medical practitioners, nor any other measure, can be effectual in preventing unlicensed and unqualified persons from practising medicine, so long as there exists a demand for the services of the latter on the part of the public.

6. That the establishment of a new and permanent board, having power to control the universities and medical corporations, is highly objectionable and uncalled for; all the real benefits contemplated by its establishment being attainable by merely enforcing uniformity as to a minimum course of study, to be determined on, after due communication with all the established licensing corporations.

7. That the proposed election of a representative body by the entire medical profes-

sion in each of the three kingdoms, could not fail to produce a regular recurrence of dissension and agitation among its members, which would interfere materially with the ordinary avocations; while those best qualified to perform the duties of a representative would be least likely to use the means necessary to secure their election, and if elected would be least able to repair, from time to time, to a distance from their homes, for the execution of those duties; whence the appointments would inevitably fall into the hands of persons in whom neither the public nor the profession would have confidence.

8. That the provisions of the bill now under consideration would, if carried into effect, gradually undermine and ultimately supersede all the existing British Medical Schools and licensing bodies, with the exception of those seated in the three capitals of the United Kingdom, by confining the power of granting licenses to practise the medical profession to those three cities exclusively, or perhaps to London alone.

9. That considering the large amount of services gratuitously rendered to the public by the medical profession, the inadequate compensation received by many of its members for their long and expensive education, and for their laborious professional exertions; considering also that each degree of Doctor in Medicine is already taxed to the extent of ten pounds; and considering finally that it is the public, much more than the medical profession, which is interested in being able to distinguish easily betwixt qualified and unqualified practitioners; the Committee is very decidedly of opinion that the expenses incurred by an improved system of medical legislation should be entirely defrayed out of the public purse, and not by tax imposed in any shape upon the profession.

The senate unanimously approved of this report, and directed that the same should be printed and circulated as extensively as possible.

Glasgow College, March 16th, 1841.

ROYAL COLLEGE OF SURGEONS IN LONDON.

THE council of the College, desirous of furnishing to the public a correct list of their members, request that each member will be pleased to transmit to the secretary, between the 1st of June and 1st of July in every year by letter, a statement containing his name at full length, address, and date of diploma, in his own handwriting, in order that it may be compared with the chronological list.

The council will be further obliged by the member stating it in a similar manner

when he has a degree in medicine, or the license of the Society of Apothecaries.

The council will be glad to receive corresponding statements from the members of the Edinburgh or Dublin College of Surgeons, practising in England or Wales.

EDMUND BELFOUR,
Secretary.

LECTURES
ON THE
PRINCIPLES AND PRACTICE OF
PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

LECTURE XXXIV.

Hydrophobia, concluded. Various questions considered respecting the disease as it appears in the Human Subject, and respecting Rabies in the Dog. Pathology of the disorder. Treatment. Preventive measures.

AFTER giving you some account of the phenomena of *hydrophobia*, or *rabies canina*, I began to notice, in the last lecture, the chief of the interesting questions which naturally present themselves to the minds of most men, and especially of medical men, in respect to that shocking disorder.

In the first place, there *is* such a disorder. It appears, too, secondly, from statements made upon credible authority, that the same group and succession of symptoms as characterize the disease, when it is produced by the bite of a rabid animal, have been observed to occur in persons who were never known to have been bitten. My own opinion is, that it is more probable that these persons had been exposed to the virus without being aware of it, than that the disease was spontaneously engendered in their bodies. I would make the same remark in regard to an instance which is said to have happened of hydrophobia in a lad who had been bitten five weeks before by a *healthy* dog: the dog remaining well at the time of his seizure and death. Mr. Youatt holds, indeed, that however the disease originated, it never occurs now, not even in the dog, except as a consequence of the application of the specific

contagion. It is certain, in the third place, that (besides the dog) the wolf, the fox, the jackal, and the cat, have communicated the disorder to the human animal. Mr. Youatt affirms, that the saliva of the badger, of the horse, and of the human being, has caused rabies; and I mentioned, on his authority, a case in which a groom contracted the disease from a scratch which he received while administering a ball to a rabid horse. But I feel much less certain about these latter animals. Respecting the dog, the fox, the wolf, the jackal, the cat, there can be no question. The result of certain experiments made at the Veterinary School, at Alfort, is opposed to Mr. Youatt's statement. Professor Dupuy made wounds in cows and sheep, and rubbed upon these wounds sponges which had been chewed by rabid animals of the same species; but he never succeeded in communicating the disorder in this way: but when he used a sponge that had been mumbled by a mad dog, then the disease occurred in the sheep and cows.

It is still more interesting to enquire, whether the saliva of a human being, labouring under hydrophobia, is capable of inoculating another human being with the same complaint? Mr. Youatt says yes: that the disease has undoubtedly been so produced. If this be so, the fact will teach us—not to desert or neglect these unhappy patients, still less to murder them by smothering—but to minister to their wants with certain precautions; so as not to suffer their saliva to come in contact with any sore or abraded surface; nor, if it can be avoided, with any mucous surface. On the other hand, all carefulness of that kind will be unnecessary, if the disease cannot be propagated by the human saliva. Certainly many experimenters have tried in vain to inoculate dogs with the spittle of a hydrophobic man: but there is one authentic experiment on record, which makes it too probable, that the disease, though it may not be communi-

cated often, or easily, is yet communicable. The experiment is said to have been made by M.M. Magendie and Breschet, at the Hôtel-Dieu, and to have been witnessed by a great number of medical men and students. Two healthy dogs were inoculated, on the 19th of June, 1813, with the saliva of a patient, named Surlu, who died of hydrophobia the same day, in that hospital. One of these dogs became mad on the 27th of the following month. They caused this dog to bite others, which, in their turn, became rabid also; and in this way they propagated the malady, among dogs, during the whole summer. Now this is a very striking fact, yet it ought not to be considered conclusive: for it is possible that the dog might have gone mad at that time, whether he had been so inoculated, or not. It may have been a mere coincidence. We want repetitions of such experiments to settle the point: nevertheless we have enough in this one experiment to make us use all necessary caution when engaged in attending upon a hydrophobic patient.

I just touched upon the question, whether the saliva of a rabid dog could produce the disease if it fell upon the *sound skin*? The first of the two cases which I related as having been witnessed by myself, would appear to give an affirmative answer to this question. Mr. Youatt thinks the disease would *not* follow such an application of the virus; but that it cannot be received upon even the unbroken surface of a mucous membrane without the greatest danger. Horses are said to have died mad after eating straw upon which rabid pigs had died. Portal was assured that two dogs, which had licked the mouth of another dog that was rabid, were attacked with rabies seven or eight days afterwards. Mr. Gillman, of Highgate, in a little pamphlet on Hydrophobia, quotes an instance from Dr. Perceval, in which a rabid dog licked the face of a sleeping man, near his mouth, and the man died of hydrophobia, although the strictest search failed to discover the smallest scratch or abrasion on any part of his skin.

At the very close of the lecture I observed, that even should it be clearly proved that hydrophobia has ever resulted from the scratch of a rabid animal's *claws*—the claws of a cat, for example—we are not to set it down as a sure thing that the disease can be introduced into the system independently of the saliva of the diseased animal. As we know that dogs and cats are in the habit of putting their paws to their mouths when they feel uneasy there, we may readily understand how the poisonous saliva may be introduced by a mere scratch with the creature's nails. Mr. Youatt believes that the saliva *only* is capable of conveying the disease.

4. Supposing the virus to have been in-

serted in the part bitten, what becomes of it? Is it immediately taken into the system, and does it, like the poison of small-pox, in some mysterious way, multiply and diffuse itself in the body, until the disease explodes? Or does it remain imprisoned in the wound, or in the cicatrix, for a time? This is an important practical question. For if the poison lurks for some weeks in the place where it was originally deposited, we might successfully remove it at any time between the infliction of the bite and the period of recrudescence. Now the facts that at this period of recrudescence the wound or scar is re-inflamed often, and almost always becomes the seat of some fresh morbid phenomena, pain, swelling, numbness, and the like, spreading towards the trunk—and that, *soon after this*, the peculiar paroxysmal symptoms begin—these facts are strong in favour of the belief that the poison does lie inert in the place of the original hurt, for some time. Dr. Bardsley states that the recrudescence pains seem always to follow the course of the nerves, and do certainly never inflame or irritate the lymphatic glands in the vicinity, though passing in a parallel course towards the trunk. He affirms the entire absence of any fact contrary to this observation in the works of the numerous authors who have written on the subject. I mention this statement, because it certainly is not correct. Mr. Mayo says, “in one case which I witnessed and examined after death, the inner part of the cicatrix was bloodshot; and a gland in the axilla had swelled at the coming on of the hydrophobic symptoms.” And I find, among my notes of Mr. Abernethy's lectures, another striking case, still more to the point. “A very intelligent boy had been bitten by a dog in the finger: he was brought into St. Bartholomew's Hospital. Caustic had been liberally used, affecting the sinewy parts, and producing a terrible sore: yet the boy was recovering himself, and the sore was healing. One day, as Mr. Abernethy was going round the hospital, he saw and spoke to the boy, who said he thought himself getting well, but that he had that day an odd sensation in his fingers, stretching upwards into his hand and arm. Going up the arm, Mr. Abernethy saw two red lines, like inflamed absorbents: they doubtless were so. He affected to make light of the matter, ordered a poultice, and recommended the boy to take some medicine. Early the next morning Mr. Abernethy visited the ward, pretending he had some other patient there, whom he wished particularly to see: and when going out again, he asked the boy, carelessly, how he was. He said that he had lost the pain, but that he was very unwell, and had not slept all night. Mr. Abernethy felt his pulse, told

him he was a little feverish, as might be expected, and asked him if he were not thirsty, and would like some toast and water. The boy said he *was* thirsty, and that he *should* like some drink: when, however, the cup was brought, he pushed it from him; he could not drink. In forty-eight hours he was dead.

Facts such as these would lead to the conclusion that, in cases in which excision had not been performed in the first instance, the scar, or the sore, might be cut out with propriety at any time before the period of recrudescence: and if the case happened to be my own, I would have this done even at that period, the moment any new sensation manifested itself in the seat of the injury. Mr. Mayo, on the same grounds, advocates the removal of the cicatrix, even although the hydrophobic symptoms may have appeared. I do not mean to say that the facts, now referred to, show with any certainty that the poison remains in the place where it was first deposited until the phenomena of recrudescence take place; but they afford some presumption in favour of that notion: and, in such a disease as hydrophobia, we are bound to act upon the very lowest presumption that affords a chance for our patient's life. The poison may be absorbed into the general system at the period of recrudescence, although no affection of the absorbing vessels or glands should be manifest: through the veins, namely.

Considering the matter philosophically, we might be inclined to suppose that the poison was silently maturing its force in the general system during the period of incubation, just as the poison of small-pox and measles are presumed to do. But looking at it practically, I should recommend, under the circumstances already stated, the excision of the cicatrix.

5. Another important question is this. Is a man who has been bitten by a mad dog, and in whose case no precautions have been taken, a doomed man? will he be sure to have the disease, and therefore to die of it? By no means. But few, upon the whole, of those who are bitten, become affected with hydrophobia.

It is curious that different species of animals appear to be susceptible of hydrophobia in different degrees. Thus, according to Mr. Youatt, two dogs out of three, bitten by one that is rabid, become rabid. The majority of horses inoculated with the virus, perish. Cattle have a better chance: perhaps because in them the skin is looser and less easily penetrated. A full half (he thinks) of those that were seized by a mad dog, would escape. With sheep the bite is still less dangerous. He reckons that not more than one in three would be affected. The tooth, perhaps, has been wiped clean in its passage

through the wool. The human being is least of all in danger. John Hunter states that he knew an instance in which, of twenty-one persons bitten, one alone became affected with hydrophobia. Dr. Hamilton estimates the proportion to be one in twenty-five. But I fear these computations are much too low. In 1780, a mad dog, in the neighbourhood of Senlis, took his course within a small circle, and bit fifteen persons before he was killed: three of these died of hydrophobia. The slaver of a rabid wolf would seem to be highly virulent and effective. These beasts fly always, I believe, at a naked part. Hence, probably, the fatality of their bites. The following statement applies exclusively to the wolf. In December 1774, twenty persons were bitten in the neighbourhood of Troyes; nine of them died. Of seventeen persons similarly bitten in 1784, near Brive, ten died rabid. In May 1817, twenty-three persons were bitten, and fourteen perished. Four died out of eleven that were bitten near Dijon: and eighteen of twenty-four bitten near Rochelle. At Barsur-Ornain, nineteen were bitten, of whom twelve died of hydrophobia within two months. Here we have one hundred and fourteen persons bitten by rabid wolves, and among them no less than sixty-seven victims; considerably more than one-half. There is no doubt, however, that a majority of persons who are bitten by a mad dog escape the disease. This may partly be owing to an inherent inaptitude for accepting it. We see some persons who, though often in the way of it, do not contract syphilis; there are others upon whom the contagion of small-pox has no influence. This difference exists, apparently, even among dogs. There was one dog, at Charenton, that did not become rabid after being bitten by a rabid dog; and it was so managed that, at different times, he was bitten by thirty different mad dogs; but he outlived it all. Much will depend also upon the circumstances and manner in which the bite is inflicted; if it be made through clothes, and especially through thick woollen garments, or through leather, the saliva may be wiped clean away from the tooth before it reaches the flesh. In the fifth volume of the *Edinburgh Medical and Surgical Journal*, there is a case described by Mr. Oldknow, of Nottingham, in which a man was bitten in three different places by the same dog; viz. in the scrotum, the thigh, and the left hand; the bite on the hand was the last. Now it seems not improbable that but for this last bite, on a naked part, he might have escaped. At least it was a remarkable circumstance that the phenomena of recrudescence occurred only in the hand and arm. The dog is supposed to have closed his mouth after inflicting the first two bites; and thus to

have charged his teeth afresh with the poisonous saliva.

It is this frequent immunity from the disease in persons who have been bitten, that has tended to confer reputation upon so many vaunted methods of prevention. Ignorant persons, and knavish persons, have not failed to take advantage of this. They announce that they are in possession of some secret remedy which will prevent the virus from operating: they persuade the friends of those who die that the remedy was not rightly employed, or not resorted to sufficiently early: and they persuade those who escape that they escape by virtue of the preventive remedy. If the plunder they reap from the foolish and the frightened was all, it would be of less consequence; but unfortunately the hope of security without undergoing a painful operation leads many to neglect the only sure mode of obtaining safety.

Mr. Youatt is of opinion that the power of the virus ceases with the life of the animal. He states, that in many dissections of the dog, the saliva, in spite of all care, must have come in abundant contact with his hands, and they were not always sound. I should strongly recommend you not to act upon this opinion: but to use the same precautions, in dissecting a rabid animal, as you would use if you were persuaded that the disease might be communicated with equal certainty before and after the death of the animal.

There are some considerations respecting this disease, which relate both to the biter and to the bitten: the canine and the human being. And there are some which relate exclusively to the dog, yet concerning which we, as medical philosophers, ought not to be ignorant. I shall advert to a few of these.

One question I have already glanced at; viz. whether the disease may be produced by a healthy, though angry dog or cat. I referred to one instance in which this was supposed to have been the case; and I repeat that I should be more inclined to think, unless we had other examples of the same kind, that the person had been inoculated in some way that he was not aware of. But I have heard Mr. Youatt describe cases in which there had been no symptoms of rabies observed in the dog at the time the injury was inflicted, though soon afterwards the animal became decidedly rabid. It is much to be regretted that the dog is so often destroyed. When a person has been bitten by a dog or cat suspected to be rabid, the beast ought to be secured, and kept under surveillance, and suffered, if it shall so happen, to die of his disease. If he does not die, in other words if he be really not rabid, that will soon appear; and the mind of the patient will then be relieved from a very

painful state of suspense and uncertainty, which might otherwise have haunted him for months or years. If the dog dies mad, the injured person will be no worse off than if the animal had been killed in the first instance: nay in one respect he will be better off, inasmuch as certainty of evil is preferable to perpetual and uneasy doubt. "Give a dog a bad name, (says the proverb) and hang him:" and it is literally so with the imputation of madness. A poor wretch of a dog is perhaps ill, or weary, or cross, or he may have been worried already by mischievous boys: the cry of mad dog is raised; and then he can expect no mercy. There are gross errors prevalent with regard to the signs of madness in the dog. If a dog be seen in a fit in the street, some person charitably offers a conjecture that perhaps he may be mad; the next person has no doubt about it; and then, woe to that dog! But Mr. Youatt assures us that the rabid dog never has fits: that the existence of epilepsy is a clear proof that there is no rabies. Again, it is a very common belief that a rabid dog, like a hydrophobic man, will shun water; and if he takes to a river, that is thought to be conclusive evidence that he is not mad. But the truth is, that the disease, in the quadruped, cannot be called *hydrophobia*: there is no dread of water, but an unquenchable thirst; no spasm attending the effort to swallow, but sometimes in dogs an inability to swallow, from paralysis of the muscles about the jaws and throat. They will stand lap, lapping, without getting any of the liquid down. They fly eagerly to the water, and Mr. Youatt states that all other quadrupeds, with perhaps an occasional exception in the horse, drink with ease, and with increased avidity. This erroneous impression is not confined to the vulgar. In the case which I have more than once alluded to, and which is mentioned in Hufeland's Journal, of a lad who died of hydrophobia after having been bitten by a dog that had not been and was not mad, one circumstance stated in evidence of the animal's freedom from rabies is, that he drank without difficulty a large quantity of water.

There is another superstitious notion not at all uncommon, viz. that healthy dogs recognize one that is mad, and fear him, and run away from his presence, in consequence of some mysterious and wonderful instinct warning them of danger. This is quite unfounded. Equally mistaken are the notions that the mad dog exhales a peculiar and offensive smell, and that he may be known by his running with his tail between his legs; except, as Mr. Youatt says, when, weary and exhausted, he is seeking his home.

It will not be out of place to state what are the symptoms of rabies as observed in the dog, and as described by Mr. Youatt.

The earliest symptoms of madness in the dog, (he says) are sullenness, fidgetiness, continual shifting of posture, a steadfast gaze, expressive of suspicion, an earnest licking of some part, on which a sear may generally be found. If the ear be the affected part, the dog is incessantly and violently scratching it. If it be the foot, he gnaws it till the integuments are destroyed.

Occasional vomiting and a depraved appetite are very early noticeable. The dog will pick up and swallow bits of thread or silk from the carpet, hair, straw, even dung; and frequently he will lap his own urine, and devour his own excrement. Then the animal becomes irritable; flies fiercely at strangers; is impatient of correction; seizes the stick or whip; quarrels with his own companions; eagerly hunts and worries the cats; demolishes his bed; and if chained up makes violent efforts to escape, tearing his kennel to pieces with his teeth. If he be at large he usually attacks only those dogs that come in his way; but if he be naturally ferocious he will diligently and perseveringly seek his enemy. According to Mr. Youatt, the disease is principally propagated by the fighting dog in towns; and by the cur or lurcher in the country: by those dogs, that is, that minister to the vices of the lower classes in town and country respectively. He maintains that if a well-enforced quarantine could be established, and every dog in the kingdom confined separately for seven months, the disease might be extirpated. This opinion is founded of course in the belief that rabies never originates at present, any more than small-pox does, *spontaneously*; but is always propagated by the specific virus. And it is corroborated by the fact that rabies and hydrophobia are unknown in some countries: I fancy that South America is, or was, a stranger to it. It appears to have been imported into Jamaica, after that island had enjoyed an immunity from the disease for at least fifty years previously; and Dr. Heineken states that curs of the most wretched description abound in the island of Madeira; that they are afflicted with almost every disease, tormented by flies, and heat, and thirst, and famine, yet no rabid dog was ever seen there. On the contrary 1666 deaths from hydrophobia, in the human subject, are stated to have occurred in Prussia in the space of ten years.

Very early in the disease, as it appears in the dog, the expression of countenance is remarkably changed; the eyes glisten, and there is slight strabismus. Twitchings of the face come on. About the second day a considerable discharge of saliva commences; but this does not continue more than ten or twelve hours, and is succeeded by insatiable thirst: the dog is incessantly drinking, or attempting to drink: he plunges his muzzle

into the water. When the flow of saliva has ceased he appears to be annoyed by some viscid matter in the fauces; and in the most eager and extraordinary manner he works with his paws at the corners of his mouth to get rid of it: and while thus employed he frequently loses his balance and rolls over.

A loss of power over the voluntary muscles is next observed. It begins with the lower jaw, which hangs down, and the mouth is partially open; but by a sudden effort the dog can sometimes close it, though occasionally the paralysis is complete. The tongue is affected in a less degree. The dog is able to use it in the act of lapping; but the mouth is not sufficiently closed to retain the water. Therefore, while he hangs over the fluid, eagerly lapping for several minutes, it is very little or not at all diminished. The paralysis often attacks the loins and extremities also. The animal staggers about, and frequently falls. Previously to this he is in almost incessant action. Mr. Youatt fancies that the dog is subject to what we call spectral illusions. He says he starts up and gazes eagerly at some real or imaginary object: he appears to be tracing the path of something floating around him, or he fixes his eye intently upon some spot in the wall, and suddenly plunges at it; then his eyes close, and his head droops.

Frequently, with his head erect, the dog utters a short and very peculiar howl: or if he barks, it is in a hoarse inward sound, altogether dissimilar from his usual tone, and generally terminating with this characteristic howl. Respiration is always affected: often the breathing is very laborious; and the *inspiration* is attended with a very singular grating, choking noise. On the fourth, fifth, or sixth day of the disease, he dies: occasionally in slight convulsions; but oftener without a struggle.

Mr. Youatt gives a detailed account of the appearances met with after death in the carcasses of these rabid dogs. They are not very constant or distinctive. The most curious and uniform consist in the presence of unnatural ingesta in the stomach; straw, hay, hair, horse-dung, and earth. Sometimes the stomach is perfectly distended with these substances; and when it contains none of them, there is a fluid resembling the deepest chocolate mixed with olive; or still darker, like coffee; and when neither the unnatural ingesta nor the dark fluid appear, it will be found, Mr. Youatt says, upon careful enquiry, that the dog has vomited much hair, hay, straw, or the like.

In 1837, a few days after the case of hydrophobia occurred in the Middlesex Hospital, I saw the carcass of a dog, that had died rabid, examined by Mr. Ainslie at his and Mr. Youatt's Infirmary. The most remarkable morbid appearances were

in the stomach, which contained some bits of straw and stick, and a considerable quantity of a dark fluid like thin treacle. In various parts of the stomach there were spots, almost black, of a considerable size; apparently produced by dark blood partly extravasated beneath, and partly incorporated with, the mucous membrane.

I believe that Mr. Youatt's opinion, already mentioned, of the cause of rabies in dogs, and in all creatures—viz. that it always results from the introduction of a specific virus into the system—I believe this opinion is not commonly entertained. Most people think that the disease is generated, *de novo*, in the dog at least, and causes have been assigned for it which certainly are not the true or the sole causes. Thus hydrophobia in the dog has been ascribed to extreme heat of the weather; it is thought by many to be particularly likely to occur in the dog-days; and many cautions are annually put forth, about that period, for muzzling dogs, and so on: very good and proper advice, but it would be as appropriate, if those who have noted the statistics of the disease may be depended upon, at one period of the year as at another. Rabies occurs nearly as often in the spring, in the autumn, and even in winter, as it does in summer. M. Trollet, who has written an interesting essay on rabies, states that January, which is the coldest, and August, which is the hottest month in the year, are the very months that furnish the fewest examples of the disease. The disorder has often been ascribed to want of water in hot weather, and sometimes to want of food. But MM. Dupuytren, Breschet, and Magendie, have caused both dogs and cats to perish with hunger and thirst, without producing the smallest approach to a state of rabies. At the Veterinary School, at Alfort, three dogs were subjected to some very cruel but decisive experiments. It was during the heat of summer, and they were all chained in the full blaze of the sun. To one salted meat was given; to the second water only; and to the third neither food nor drink. They all died; but none of them became rabid. Nor does the supposition that the disorder has some connexion with the period of sexual heat in these animals appear to have any better foundation.

If you are desirous of knowing what my own opinion on this matter is, I must say that I think Mr. Youatt's doctrine by far the most probable one; that rabies never occurs except from inoculation of the specific virus. It has never been proved, and indeed it would scarcely be susceptible of proof, that the disease ever breaks out spontaneously; large tracts of country are totally free from it; and in 19 cases out of 20, perhaps, we trace the

bite or the fray in which the inoculation has been effected.

If I were asked to define the seat of this terrible disease, I should place it, without hesitation, in that division of the nervous system which comprises the excito-motory apparatus; the true spinal marrow, with its appendages of afferent and efferent nerves. Nay, I should go farther, and say that it is the upper part of this apparatus, of which the functions are primarily and chiefly deranged: that the poison acts mainly upon the nervous arcs which pertain to the throat, and with which the eighth pair of nerves in particular is connected. There is nothing singular in this localization of the influence of a specific poison. The ergot of rye affects principally those arcs which belong to the uterus; cantharides those which govern the muscular fibres of the bladder. It is true that the mental functions are remarkably modified, and that paralysis of the lower extremities occurs, in most instances of the disease. But neither of these phenomena are constant; and they simply illustrate, when they do happen, the facility with which any morbid state of the spinal cord may propagate its influence in either direction. Whether, in hydrophobia, the essential change be centric or eccentric, cannot be determined with any thing like certainty: but it seems to me to be most probable that the sensibility of the afferent nerves of the fauces, of the skin, and of the air-passages, is altered or morbidly exalted; whence, upon the application of the exciting stimulus, the peculiar sighing dyspnoea, and the strangling dysphagia, are produced by a reflected influence through the central axis upon the muscles concerned in these actions. But, as I said before, the pathology of the excito-motory apparatus is as yet in its new birth.

What can I say of the *treatment* in hydrophobia; or in rabies? There is no well-authenticated case on record, that I am aware of, in which a hydrophobic person has recovered. As it has been, so it is still, *ιαρος ιαται θανατος*. The physician that cures is death. There can be no ground therefore for the recommendation of any especial drug, or form of medicine, or even for any general plan of treatment, after the peculiar symptoms of the disease have once set in.

Of course those powerful remedial agencies that are in common use among medical men, have been fairly tried: copious blood-letting, mercury, opium, arsenic, sugar of lead, oil of turpentine, the cold affusion even: and not only those, but the strong poisons that are sometimes, but not so generally, employed for other diseases; belladonna, stramonium, prussic acid,

white hellebore, strychnia, cantharides, the nitrous oxide gas: and no end of less gigantic remedies; such as alkalies, and especially ammonia, carbonate of iron, electricity and galvanism, tobacco-juice, and the guaco (which was introduced into this country a few years ago with high encomiums for its power over the disease), the mineral acids, violent exercise: and if we take into account the substances administered to the brute also, we may increase this list by the alisma plantago, scutellaria, box, and rue, all of which, at one time or another, have been vaunted as successful remedies, veratrum sabadilla, and ticunas poison.

The difficulty of swallowing fluids, and in some cases of swallowing at all, is a serious obstacle to the fair trial of almost every form of internal remedy. It has been proposed to introduce powerful medicines into the rectum, in clysters: but to this also the patients have been found to make great resistance. The injection of medicines into the veins has been tried; Magendie hoped that he had discovered a cure, in first largely bleeding the patient, and then injecting his veins with a corresponding quantity of warm water: but it has always happened with this, and with other promising experiments, that just as the patient seemed to be about to recover, he has died. The nervous irritability has in one case or two been much calmed by the injection of a solution of the acetate of morphia into the veins.

Mr. Mayo has suggested bronchotomy: upon this ground, (to use his own words) "that the principal character of the disease, and the rapid exhaustion which attends it, appear to depend in great part upon the fits of spasm and closure of the glottis, brought on, not merely by the attempt, or the idea of drinking, but by any sudden impression upon the senses. Now it is clear, he adds, that as far as the distressing feelings in the throat consist in a sense of suffocation, they would be put an end to or relieved by the establishment of a free opening in the windpipe." Dr. Marshall Hall would use, in combination with tracheotomy, the hydrocyanic acid. Now I should be sorry to say any thing to damp your reasonable hope of benefit from any experiment; but I am bound to confess to you that I should not expect the smallest advantage from tracheotomy in this disease. The mode of death offers no encouragement to its use. There may be spasm of the glottis, but I doubt it; at any rate the patients do not die of suffocation; the death is not death by apnoea, but by asthenia. We see persons labouring grievously for their breath for hours together, who yet survive, and are presently themselves again; persons,

for instance, who are affected with severe spasmodic asthma. I have seen a man sitting up in bed a whole night long, inspiring with such difficulty that, if I had not been aware of his having scores of times been as bad before, I should have thought he could not exist five minutes longer. Now we have nothing of this dyspnoea in hydrophobia: and, as I said already, I am sorry, and diffident too, when I differ from great authorities on practical points, but I see no hope of cure, nor even of sufficient benefit, to counter-balance the inconvenience and hazard of the operation, from the performance of bronchotomy. The principle is that of suffering the parts gradually to recover themselves, and of allowing the patient in the meanwhile to breathe through another channel. The principle is excellent, (as I shall shew you by and by,) where there is a permanent obstacle to the admission of air to the lungs through the larynx; but in hydrophobia there is no such permanent obstacle to surmount. Though your patient, in laryngitis, should be at the point of death, yet open his wind pipe, and he breathes again and is safe; but it is not at all uncommon for a hydrophobic patient to lose his spasms, to swallow well, and to breathe easily, yet he does not recover. This amendment is the prelude of death, the last flicker of the expiring lamp. Since I lectured upon this subject last year, Dr. Latham has told me the following circumstance respecting a patient whom he treated for hydrophobia, in the Middlesex Hospital. He went one day to the ward, fully expecting to hear that the patient was dead. But he found him sitting up in his bed quite calm, and free from spasm; and he had just drunk a large jug of porter. "Lawk, sir, (said a nurse who sat by) what a wonderful cure!" The man himself seemed surprised at the change. But *he had no pulse*; his surface was cold as marble. In half an hour he sunk back, and expired. Furthermore the experiment in question has been tried, and it has been tried by its proposer Mr. Mayo, upon the dog, without affording, as Mr. Youatt assures us, the slightest relief. In the matter of cure, surgery, I fear, is as impotent as physic.

Not so, however, in the matter of prevention: this is the most important part of the practice. The early and complete excision of the bitten part is the only measure in which we can put any confidence: and even here we are met with a source of fallacy. In the majority of cases, no hydrophobia would ensue, though nothing at all were done to the wound. How can we know, then, that the disease is ever prevented by its excision? No doubt many persons go

through the pain of the operation needlessly. But we can never be sure of this. They get at any rate relief from the most harassing suspense, with which they would be probably tortured for months. And if a large number of bitten persons, who had suffered the wound to heal as it would, could be compared with the same number who had had the bitten part cut out, hydrophobia would be found a frequent consequence of the bite in the first class—a very rare consequence of it in the second. Mr. Youatt, who trusts to caustics, and who has himself been bitten seven times, and is yet alive and well, tells us that he has operated, with the caustic, on more than four hundred persons, all bitten by dogs, respecting the nature of whose disease there could be no question; and that he has not lost a case. One man died of fright, but not one of hydrophobia; and he says also that a surgeon of St. George's Hospital told him that ten times that number had undergone the operation of excision there, after being bitten by dogs (all of which might not, however, have been rabid), and that it was not known that any one had been lost. Mr. Youatt, I say, trusts to caustic; and the caustic he uses is the nitrate of silver. But I advise you to trust to nothing but the knife, if the situation of the bite will allow you to employ it effectually. If the injury be so deep or extensive, or so situated, that you cannot remove the whole surface of the wound, cut away what you can; then wash the wound thoroughly, and for some hours together, by means of a stream of warm water, which may be poured from a tea-kettle; place a cupping-glass from time to time over the exposed wound; and finally apply to every point of it a pencil of lunar caustic. If you cannot get the solid caustic in contact with every part, you had better make use of some liquid escharotic; the nitric acid, for example. In my own case—and what I should choose for myself I should advise for another—if I had received a bite from a decidedly rabid animal upon my arm or leg, and the bite was of such a kind that the whole wound could not be excised, my reason would teach me to desire, and I hope I should have fortitude enough to bear, amputation of the limb, above the place of the injury.

But if the wound is of such a size, and in such a part, that it can be excised, what is the proper way of cutting it out? If I were to give you any opinion, as from myself, upon that point, you might think, perhaps, that I was stepping beyond my proper province. I shall, therefore, again retail to you the advice of my old master, Mr. Abernethy. "The cell (he says) into which a penetrating tooth has gone, must be cut out. Let a skewer be shaped, as nearly as may be, into the form of the tooth, and then be placed in

the cavity formed by the tooth; and then let the skewer, and the whole cell containing it, be removed together by an elliptical incision. We may examine the removed cell, to see if every portion with which the tooth might have come in contact has been taken away: the cell may even be filled with quicksilver, to see if a globule will escape. The efficient performance of the excision does not depend upon the extent, but upon the accuracy, of the operation." Mr. Abernethy was of opinion that when once the poison had been imbibed into the system, nothing ever had done good, and nothing, probably, ever would. I should be sorry to be so absolutely despairing in respect to a disorder in which dissection after death discloses no reason why the patient *might* not recover. He used to add, that as bleeding had been much extolled, had he hydrophobia he would allow a surgeon to bleed him, even to death. Like Seneca he would be willing to have his veins opened, though his disease might not permit him to indulge at the same time, like Seneca, in the luxury of a warm bath.

I say *early* excision is the only sure preventive; but let me repeat that it will, in all suspicious cases, be advisable, if, for any reason, the operation has been omitted in the first instance, to cut out the wound, or the cicatrix, at any time before the symptoms of recrudescence have appeared. One would do it, though with less hope, as soon as possible *after* they had appeared: but I do not expect to hear of excision being successful then in stopping the disease. Dr. Bright has recorded a case in which the arm was amputated upon the supervention of tingling, and other symptoms, in the hand, in which the patient had been bitten some time before; but the amputation did not save him.

It has been proposed to fill the wound with ink, and then to wash it until every trace of the ink is gone; in this way, it is conceived, the complete ablation of the poison also will be ensured. With a timid or an obstinate patient, who would not submit to the knife or the caustic, some such expedient ought to be diligently tried: but it would be better to try it *after* the excision, or after the application of the escharotic substance. It is impossible to take superfluous pains to obviate so fearful a disease as hydrophobia.

It has been recommended, after the wound has been excised or cauterized, that it should be prevented from healing, and made to discharge for a long time, by means of irritating applications. This may be advisable when thorough excision, or complete cauterization, cannot be effected; but I should think it quite useless as auxiliary to those expedients, and only likely to keep up, or to produce, a hurtful irritability of the system.

I should perhaps have mentioned before, a theory, and a plan of preventive treatment, which made a great figure in all the journals, foreign and domestic, a few years ago. It was pretended by a Russian physician, Dr. Marochetti, that some time between the third and the ninth day after a person had been inoculated with the hydrophobic poison, by the bite of a rabid dog, small pustules appear on or about the frænum of the tongue, containing a small quantity of sanious fluid, of a yellow or greenish colour. The same kind of pustules were declared to exist also under the tongues of the mad dogs themselves. Now Dr. Marochetti pretended farther, that if, from the very time of the bite, you gave the patient large doses of the decoction of broom tops, and looked out for the eruption of these pustules, which seldom lasted more than twenty-four hours, you might infallibly prevent the disease by opening and emptying the pustules, and then cauterizing them with a red-hot iron; and afterwards causing the patient to gargle his mouth with that same decoction of broom. He held that the poison was deposited there for a short time, and then reabsorbed into the system; and he proposed to prevent such reabsorption. This was a very pretty theory; and took nightly in the medical world. But it has turned out a sort of hoax. I do not mean a wilful hoax on the part of Dr. Marochetti; for I have no doubt that he contrived to hoax himself. These pustules have been looked for again and again; but they have never been discovered in Englishmen affected with hydrophobia; nor in English mad dogs. The truth seems to be that the mucous follicles of the mouth, generally, and those at the base of the tongue, and those beneath the tongue, in particular, are commonly enlarged and exaggerated in the dog, and in the human animal, labouring under the disease; and these enlarged and altered follicles were regarded by the Russian physician as a specific eruption, that furnished the virus and pabulum of the complaint.

As almost every drug that has ever been included in any Pharmacopœia has been administered with the hope of *checking the disease*, so a great number of medicines and measures have been praised as preventives. Some people have great faith in sea bathing; and they go to the coast to be ducked and half drowned every day for six weeks: and if they escape hydrophobia they conclude that the immersion in the salt water has saved them. Some of the specifics, as you may suppose, are great secrets; and they who possess them—whether they believe in them or not is another matter—sell them at no cheap rate to those who have been bitten by the dog, and are weak enough to be bitten again by the quack. The compo-

sition of several of them has transpired; and they are found to consist either of ingredients the most insignificant and worthless, or of poisons of which the inefficacy had already been ascertained. The celebrated *puleis antilyssus*, which was introduced by no less a person than Dr. Mead, into the London Pharmacopœia, was a mixture of ash-coloured liverwort and black pepper. The *Ormskirk medicine*, long famous, and scarcely obsolete yet in the north of England, was made up of bole armeniacæ, alum, chalk, elecampane, and oil of aniseed. The *Tonquin medicine* was composed of cinnabar and musk; and the *Tanjore pills* were a combination of mercury and arsenic. Even now scarce a year elapses but some correspondent of the newspapers, whose philanthropy is more conspicuous than his judgment or his knowledge, recommends a new and infallible preventive. I confess to you that I have not the slightest faith in any one of them; but as I have a great respect for Mr. Youatt, and as he is not *quite* so sceptical as I am on this point, and as patients or their friends will insist upon the adoption of protective measures sometimes, when the local means of prevention have been omitted or imperfect, I will tell you what he (Mr. Youatt) has done in respect to those prophylactic drugs.

In the first place he never succeeded in curing the disease in the dog with any thing that he ever tried.

In the way of prophylaxis, he experimented with a great number of substances. He thought that the box-wood, which is the basis of some celebrated preventive drinks in Hertfordshire and Kent, had some effect. He tried the *alisma plantago*, the boasted efficacy of which had been strictly inquired into by the magistracy of Toula, and the receipt purchased by the Russian Government at an immense price. But he had no success with it. He then put the belladonna to the test, beginning with two grains, and increasing the dose to a scruple twice every day, and continuing this for six weeks: and he says he is confident that he saved several dogs; but he lost almost as many. They all became debilitated and most rapidly emaciated.

Then, in the year 1820, his attention was directed to the *scutellaria lateriflora*, which Dr. Spalding, an American physician, had found highly successful as a preventive of rabies: and upon trial of it, he soon was brought to regard it as really valuable: and (not to tire you with a detail of his proceedings in the interim) he at length combined it with belladonna; "and the result," (I here quote his own language) has been a medicine which I cannot, dare not, call a specific; for it has failed: but the use of which, in the cases of doubt and fear to

which I have alluded, I would most earnestly recommend." He relates two experiments, which seem to have made a great impression upon his mind. They are as follows:—

"Three pieces of tape were thoroughly moistened with the saliva of a rabid dog, and inserted as rowells in the polls of three dogs. To two the scutellaria and belladonna were given: the third, a fox-hound bitch, was abandoned to her fate. On the 29th day after the inoculation she became rabid." The others, at the time this was written, *i. e.* some months afterwards, were living and well.

He afterwards took the same two dogs, and a third. He moistened two pieces of tape with the saliva of a rabid dog, and inserted them in the polls of one of the old dogs, and of the third dog. Another piece of tape dragged repeatedly through the mouth of the same rabid dog *twenty-four hours after its death*, was inserted in the poll of the second of the old dogs. This dog and the new one were suffered to take their chance. To the other old dog the medicine was given. In the fourth week the new dog died undeniably rabid. The other two survived.

I repeat that I have no faith in these preventives. But *sometimes* some of them must be tried; and I would prefer those which are thus sanctioned by Mr. Youatt's good opinion to any others.

And with respect to the established disease, I think that if I were the unhappy subject of it, I should wish to be put into a hot air bath, and thoroughly sweated, and to take opiates; not so much in the hope of recovering as with a view to the euthanasia. But, with all respect to those gentlemen who advocate that practice, no one, if I could help it, should make a hole in my wind-pipe.

CLINICAL LECTURES,

BY DR. CORRIGAN,

*Delivered at the Hardwicke Fever Hospital,
Dublin,*

During the Session, 1840-41.

LECTURE VII.—FEVER, No. 5.

Case of Gray; post-mortem examination of, shewing that death had occurred without any structural lesion. Follicular Enteritis; case of Mary Cope; case of Purcell; treatment of, by sponge suppositories; case of Graham; peculiar form of Pneumonia.

IN accordance with the analysis we have made of fever, we should come now to the derangement of the function of respiration; but, before going into general observations, I wish to direct your attention to three cases, which have occurred within the last fortnight, which

are connected with the pathology of fever, and one of them more particularly with the immediate subject before us.

The first of these cases is that of William Gray, a groom, *ætat.* 40. He was admitted on February 11th, then ill three days. He was suffering under very great prostration of strength; his face was congested, the depending portions of the body and extremities were of a livid red colour, and the surface was cold. The maculæ were few and pale, and badly developed; his pulse was very quick and weak; respiration was scarcely disturbed; there was no tympanites. He had not delirium. He slept, and he complained only of slight headache. On the previous Monday, in his passage over from England, he had been much exposed to cold and wet. Notwithstanding all endeavours to rouse him, by wine, blisters, bark, and ammonia, his pulse continued to grow feebler; but he slept, and he was not delirious, until a few hours before his death, when he became comatose, and died on the second day after his admission into the hospital, the fifth day of his illness.—This man was completely struck down by the severity of the fever. It was the worst, the most rapidly fatal case of typhus, we had had in the hospital for many months; yet what did we find on examination of the body of this patient? No organic disease any where. The brain was perfectly sound; the heart was remarkably firm and muscular; and the most careful examination could detect no trace of disease in the intestines. So little tendency, indeed, was there to any affection of the glands of the intestines, that they were not even sufficiently developed to enable us to detect them with the naked eye. In the lungs there was some amount of hypostatic congestion, but this was all the most careful examination could discover. Structural pathology, then, tells us nothing of the cause of death in this case: there was no local alteration of structure to which by possibility could even be referred the symptoms or death of this individual; but, if we apply to the case functional pathology—if we use in considering it the analysis we have already made of fever—we can understand its nature. From the very commencement of the case there was a sinking of one of the most important functions of the living body—the circulation. The capillaries had completely lost their tone; mere gravitation they were even unable to contend against; the depending portions of the body were everywhere of a livid red; and even in the face, where there might have been expected to be some action, there was so little, that, while the vessels were distended with blood, there was scarcely any development of animal heat; the surface was cold; the state of the function of circulation through the whole system, seemed, in truth, to be one of

complete atony. This state of so important a vital function, the distension of the capillaries, and the want of almost any development of animal heat, made me mark the case on its very admission as one of a hopeless character. There is no necessity for seeking for structural change to account for death in such a case. There is no difficulty in understanding that death, in such case, will follow from the sinking of so important a vital function as circulation; no more difficulty in supposing death to be the result of this functional derangement, than there is in admitting death to follow on the structural derangement which is the result of pneumonia or peritonitis, or any other local structural disease; indeed, less; for, in the case before us, the affection of so important a vital function is general through the whole body, while, in a local disease, the morbid alteration is confined to a particular and, perhaps, a small space.

This case is, I think, a valuable one for our information: we found no structural lesion in a case of typhus fever so aggravated as this. Had we found any, we might still have had before us the "*vexata questio*," as to whether the local disease was the effect or the cause of the typhus fever. Here we found none. It therefore follows, unequivocally and undeniably, that typhus, or maculated fever, as we now have it, may not only exist, but be fatal, without local organic disease: in other words, it proves incontestibly the truth of our analysis, that our present typhus, or maculated fever, is a disease of function; that it has no structural pathology. There are some very interesting points connected with the nature and alteration of the urinary secretion in this case; but we must reserve these for another time.

The next case, Mary Cope, shews to us the exact nature of a disease of the mucous membrane of the intestines, which is sometimes one of the most fatal of the sequelæ of our fever, viz. follicular enteritis. This woman, *ætat.* 22, previously in the enjoyment of the best health, was admitted into the hospital on the 23d January, ill of maculated fever. There was nothing unusual in her case. She was marked convalescent, when, about fourteen days before her death, she complained of debility and diarrhœa; her tongue became brown and dry in the centre, but not furred; there was no tenderness of the abdomen, nor tympanites, but there was gurgouillement over the cœcum; the stools were gruel-like, but were not observed to be mucous or bloody; there was no tenesmus; her pulse became very quick and weak. She became so debilitated on the 18th February as to require wine in considerable quantity. All means to stop the diarrhœa were of no avail, and she died on the 19th February.

On dissection, the peritoneal coat of the

abdominal viscera was sound; but the small intestine, the ileum, and the large intestine, presented (as you saw) the finest specimen of follicular enteritis in every stage. In some places the follicles were just protruding under the mucous membrane, filling with a cheesy purulent-looking matter; in others, this matter had amounted to such a quantity as to make each follicle protrude the mucous membrane, as if a pea were lying under it, while it felt hard and firm to the finger passed over it; while, in others, still farther advanced, one or more had gone on to ulceration, destroying the mucous membrane, and leaving only a grey slough of cellular tissue in the place of the follicle. The whole circle of the ileo-cœcal valve was one circular jagged ulcer: there were several small ulcers in the wider extremity of the appendix vermiformis. This appendix was swollen and congested externally; and, on slitting it up, it was found distended with a tenacious, lymph, purulent fluid. In the ileum, a little above the ileo-cœcal valve, were several circular or oval ulcers, apparently resulting from the destructive process having attacked patches of the glandulæ agminatæ; while around, and still higher up, were a few of the glandulæ solitariæ similarly diseased (but less in degree) to those in the colon. The greatest intensity of disease was at the ileo-cœcal valve. Both above and below this, the diseased appearance gradually grew less marked. The state of the appendix vermiformis, in this case, explains, I believe, what I lately observed in a case in private practice, in which the patient, a lady, was attacked, after partial recovery from fever, by follicular enteritis, as in the instance of Cope. During the progress of the case, the nurse-tender called my attention to what she believed to be a worm passed per anum, but, on examination, I found it to be a cord of lymph, about as thick as a quill, and from two to three inches long. It was quite solid. A similar substance was passed twice, or oftener, at intervals of two or three days. It is very probable that it was secreted in the appendix vermiformis and expelled, and a similar one again re-formed.

We have had several cases like Cope's, but all recovered except this one. Purcell, to whose case I have already alluded, was a well-marked instance of the same disease, coming on as a sequela of the fever; but no one who has seen Cope's or Purcell's case could for a moment confound it with typhus fever, or suppose the disease to be the pathology of maculated fever. Follicular enteritis is a local disease marked by as distinct symptoms, and as different from typhus fever, as any local disease to which the living system is subject. I have wished you to notice this case, as it bears upon a point we have previously discussed;—the supposed dependence of typhus on follicular disease of the intes-

tines.—I may make a few short observations now on the treatment of this follicular disease of the intestines. There is one remarkable feature about it, and that is, the difficulty of salivating a patient labouring under it; and this you may generally take in most diseases as an indication that mercury is a remedy in such diseases of doubtful, if not of injurious, action. The treatment which we adopted in Purcell's case, which was one of very great severity, and in the others, and which proved successful in all but Cope's case, was the continued administration of small doses of opium or Dover's powder, with counter-irritation repeated over the abdomen and right iliac region particularly, and the mildest farinaceous diet. In some cases, all ordinary means, whether by medicines given by the mouth, or in the form of enemata, are of no avail to check the diarrhoea, and the patient is fast sinking under it, when it will be rapidly and efficiently averted by the introduction into the rectum of a piece of sponge, about the size of a small hazel-nut, soaked in a solution of watery extract of opium. This will at first require to be renewed perhaps three or four times a day, but most often only once after the second day.

The third case to which I have to direct your attention is one of considerable importance, both as regards itself, as to its own peculiar nature, and also in relation to the insight which it gives us into a state of the respiratory and circulating functions of frequent occurrence in our maculated fever.

Mary Graham, a servant, æt. 21 years, was admitted into the hospital, Jan. 1841, in an apparently dying state: she was in a state of great relapse: her limbs and hands were livid; the surface generally cold, and she was almost pulseless: she was suffering very much from cough and dyspnoea. With great difficulty, from her being scarcely able to articulate, she informed us that, about three weeks before, she had been attacked with pain in the left side and oppression of breathing, for which she had been bled, with temporary relief; but soon after, the oppression continuing to increase, she was removed to the hospital. On a physical examination, the chest appeared to be well formed: over the anterior portion of the left clavicular region, and to the lateral and posterior inferior region of the same side, there was dulness to the greatest degree. Over a great portion of the left lung there was some crepitating rattle, but not fine, nor heard plainly over the whole extent of the dull region, nor was there bronchial respiration audible in the dull sounding parts. The infra clavicular region, after a few days, cleared on percussion, muco-crepitating rattle was heard, and the expectoration became muddy and sanguineous, but she never rallied; she was kept alive only by wine and carbonate of

ammonia, and an attempt was made at the same time to get her under the influence of mercury. She died on the 31st of January. —The right lung was very nearly sound. The heart was greatly enlarged as to the size of its cavities, but there was no valvular disease. The superior portion of the upper lobe of the left lung was not much congested, but from this, downwards, constituting probably three-fourths of the lung, and extending through the middle into the inferior portion of the lower lobe, the substance of the lung was in a singular form of pneumonia. The pleura was quite free from any trace of disease. The substance of the lung, viewed through it, was of a dark blue or purple colour. Its substance was tough, not in the slightest degree brittle, not crepitating, and, when thrown into water, it sunk like a hepatized lung. Very little fluid exuded from it when cut into. In the neighbourhood of the diseased portion, and in some places mixed with it, were a few small nodules of pulmonary apoplexy. Now, this was not the first stage of ordinary pneumonia, for it was not crepitating; it did not pour out fluid in an abundance when incised; it was not of the same colour. It was not hepatization, either red or grey, and still less did it bear any resemblance to the third stage of pneumonia. The case was, it will be remembered, also of three weeks' standing, when, in the ordinary form of the disease, it should have gone on to hepatization, or even farther. If we couple the history of the case with the general symptoms, we can, I think, arrive at a knowledge of its nature. The patient, brought from one of the most wretched abodes in the city, the neighbourhood of Mary's Lane, had herself bled for a commencing attack of pneumonia three weeks previously, and after this continued suffering under cold, damp, and probably want, in the severest season of the year. From this state she never rallied, neither did the distended capillaries of the affected lung. They remained in their congested state; there was no attempt at any of the ordinary changes, or the usual progress of pneumonia; they passed at once into a state of hyperæmia, and they remained in this state; in fact, they were in a state similar to that of the capillaries in an extremity that is affected with atonic congestion of its capillaries—a state that we see, on a small scale, in the capillaries of the skin, in depending portions of the body, in a case of typhus fever.

The appearance of the lung on post-mortem inspection coincided exactly with this; it was exactly such an appearance as would be produced by the capillaries passing into a state of congestion, and obliterating the air-cells; not as they are obliterated or filled up in ordinary pneumonia, but obliterating them by pressing in, from their distension, on the air-cells. The lung thus became solid.

and dull as muscle, dark in colour, and remained at the same time tough. The closing together of the air-cells was probably also facilitated by the great debility of the patient; her strength being exhausted, she dilated only the healthy portions of the lung, and thus the passive distension of the capillaries was in no way counteracted by the respiratory efforts drawing in air to the air-cells in the diseased portions of the lung. This weakness of respiratory effort will also account for the absence of bronchial respiration in the solid portion of lung. This case is very interesting, both on its own account, and from the light which I think it will throw on a similar state of the lung in fever.

ON STAMMERING,

AND THE METHODS PROPOSED FOR ITS
REMOVAL.

By EDWIN LEE, Esq.

[Continued from p. 269.]

[For the *Medical Gazette*.]

SOME cases of paralysis, which serve to illustrate the destruction or interruption of the harmony existing between sets of muscles which are naturally associated in their actions, are thus referred to by a modern writer on the nervous system:—

“C’est ainsi que certaines paralysies partielles, en détruisant l’harmonie fonctionnelle, dénaturent les directions et l’équilibre; j’ai vu souvent dans de telles paralysies les médecins croire, d’après M. Flourens, a une lésion du cervelet, parcequ’ils remarquaient que l’équilibre étoit rompu; ou que les mouvemens n’étoient pas convenablement *balancés*; ou auroit pu croire aussi dans ces cas, en voyant l’individu manœuvrer autrement qu’il ne vouloit, que l’organe des directions étoit lésé; mais en observant mieux, il ne reste aucune incertitude à ce sujet; on s’aperçoit que les directions sont appréciées voulues et indiquées, mais que l’indication n’est nullement suivie, non par ineptie, mais par défaut d’ensemble des instrumens d’exécution, dont les uns sont plus ou moins faibles, ou manquant totalement à leur mission, et dont les autres manquant d’antagonisme ne sont pas pondérées; de là ces mouvemens brusques saccadés, ou trop énergiques sans mesure ni précision, qui lancent les paralytiques incomplets dans des directions qu’ils n’ont pas résolues, par la desharmonie d’action

le non-concours régulier, la non-coordination entre les instrumens d’exécution, dont les uns répondent mal ou même ne répondent pas aux directions imprévues, et dont les autres n’étant pas pondérés par leurs antagonistes, agissent trop vivement; il y a donc bien là non-coordination, mais non pas à la manière dont l’entend M. Flourens, qui place à tort la faculté coordinatrice dans le cervelet, au lieu de la direction des mouvemens en avant*.”

We may thus see, from what has preceded, that speech is dependent upon a variety of movements; and that for its formation, not only is harmony required between muscles completely under the control of the will (as are those of the lips and tongue), but also between such muscles and others which are but partially so: a free respiration, a regulated contraction of the muscles of expiration, of those of the larynx, palate, tongue, cheeks, and lips, in obedience to volitions conveyed to several of them simultaneously, or in rapid succession, being necessary for perfect articulation. It will therefore excite no surprise, on considering these circumstances, that speech should be so frequently affected in various diseases, and by various conditions of the nervous system, which destroy or interrupt, for a longer or shorter period, the harmonious action of these several parts. Persons labouring under concussion of the brain, apoplectic attacks, in the debility caused by exhaustion, or which supervenes in the latter stage of acute disease, can very frequently put out their tongue, and move their lips, but are unable to perform the associated actions required for speech, which inability is likewise frequently a premonitory symptom of paralysis or cerebral disease. After active exercise, as running, a person will frequently be speechless for some time, not merely from the want of air, but also from the temporary disorder or exhaustion of the nervous energies. The same circumstance may occur from mental emotions, as fear, surprise, agitation, and may even last for a long period; as the effect does not always cease with the action of the causes which produce it. When these causes act in an aggravated degree, they may induce loss of power over the more strictly

* Sarlandière, op. cit. Paris, 1840.

voluntary muscles, as those of the extremities, and the individual will be unable to move*. I have entered more fully into the consideration of these points in my work on Nervous Disorders, and will terminate these remarks by quoting from it a passage or two bearing upon the present inquiry. "Those parts which, though necessary for the performance of ordinary actions, are not so directly controlled by the will as some others, and hence require more exertion of this faculty for the healthy performance of their functions, appear to be most liable to be affected by its debility. Thus it has seemed to me that the muscles of the larynx are more subject to atony than the muscles of the extremities, when moral causes have been instrumental in producing the affection, and that the inferior extremities are more frequently affected than the superior."

"Loss of voice, depending on a state of atony or paralysis of the small muscles of the larynx, from suspension of their nervous power, is of frequent occurrence. It may be total or partial, in which latter case the patient can make himself understood in a low whisper. The lips and tongue can be freely moved in this variety of aphonia. It may supervene upon mental emotions, convulsive or other nervous affections, irritation of the surface, or of viscera; or it may come on without any obvious cause. A case is mentioned, in the *Dictionnaire de Médecine*, of a lady who was deprived of her voice during several years from excessive joy succeeding a state of great anxiety, which resisted all the means employed for its relief, and disappeared, when least expected, after strong emotion. In another case, the patient, during fourteen years, could only speak, every day, between the hours of twelve and two or three. Some years ago I saw a young man who suddenly lost his voice completely, for which no cause could be assigned. I stated that, although he might not derive relief from medicine, that the voice was not unlikely to return at some future period. This has since

occurred, after an interval of twelve years from the attack. M. Ollivier mentions a case of intermitting aphonia which, he says, 'existed more than thirty years, and was only cured for the time by abstraction of blood.' He adds, 'what is curious, however, is, that the voice suddenly returned after one or two spoonfuls of blood had flowed.' In this case it can hardly be supposed that the quantity of blood lost could have had any influence in the restoration of the voice; and I am inclined to believe that it was in consequence of the impression on the patient's mind that the voice must necessarily return at the time of the bleeding. The long duration of the disorder may be ascribed to the habit of having it recur at stated periods. These cases also tend to corroborate the opinion of their nature which I had been led to entertain, and there is every reason to believe that, could the patients' minds have been diverted from the expectations of the attacks at the accustomed period, they would not have occurred."

I might adduce several other cases illustrative of the action of mental impressions in the production and removal of disorders of the voice and speech; but as such would be out of place on the present occasion, I will merely extract the following from another of my works, as serving to exhibit the powerful influence of the imagination over those disorders.

"Aphonia of six weeks' duration cured in a few hours by starch pills given homœopathically.—A girl, æt. 20, was admitted on the 14th of January, with complete loss of voice, which had existed since the middle of November. She had experienced a similar attack in the preceding year, but had recovered in fifteen days. The menstruation was regular. A few days rest, and the usual hospital regimen, producing no effect, she was consequently placed in the department where the homœopathic experiments were made, and was ordered two pills composed of starch, which she believed homœopathic remedies. The first to be taken in the presence of the physician, the other at the expiration of four hours. A few minutes after the first pill had been swallowed the following symptoms manifested themselves:—Anxiety, pain, and uneasiness in the region of the heart and thorax; perspiration, with heat and eruption on the

* The fascination of some birds by the aspect of certain serpents rendering them unable to escape, or even to keep their position upon the tree, is in consequence of volition being paralysed by fear. The same circumstance occurs, in a minor degree, when an individual becomes speechless from strong mental emotion.—*Treatise on some Nervous Disorders*, &c. 2d edition, 1838.

skin. The second pill appeared to aggravate these symptoms, with the addition of hiccough. She afterwards fell asleep, and on awaking she was astonished to find she could talk in a loud tone. The complaint did not recur, and she soon quitted the hospital*."

Similar cases to the above will not of course be confounded, by the discriminating practitioner, with the loss or alterations of the voice and speech arising from obvious local irritation reacting upon the spinal cord or nerves, as in the instances of traumatic tetanus, worms in the intestines, &c.

On Stammering.

This affection has been confounded with the hesitation, difficulty of expression, or repetition of words—*balbuties*, which so commonly occurs in children in their first attempts to talk, and which generally ceases as they grow up; though, in a few instances, stammering supervenes upon it, which leads parents, and those who have the charge of them, sometimes to say, that the stammer has existed from the time they began to speak, which is not the case. A degree of hesitation, difficulty, or stuttering, may arise from other causes—as bashfulness, stupidity, confusion of ideas, apprehension, surprise, &c. which may occasion considerable embarrassment in the articulation of words; and, as a foreign author has observed, "it frequently happens even in persons highly endowed, and who usually express themselves with facility, to be wanting, as it were, to themselves, and to stammer out with difficulty the most trifling excuse, the most simple compliment, or the most ordinary answer to a question, which requires on their part some little presence of mind†." The imperfect articulation in certain states of cerebral congestion, inebriety, or weakness from disease, must also be distinguished from stammering.

Stammering, then, as may be inferred from what has preceded, may be considered as a spasmodic affection in the great majority of cases; not, however, of that kind which is caused by irritation of the surface, or of internal parts, or by lesions of the nerves or

spinal cord, but of a cerebral origin, and depending upon a temporary disorder or a faulty action of the faculty of volition, as far as certain muscles employed in respiration and articulation are concerned, which induces a want of consent or harmony of action between these muscles and others, which are more directly under the influence of this faculty*. In the peculiarities which it presents it has great analogy with other nervous affections, especially chorea. It seldom occurs before the age at which children possess consciousness, and are able to pronounce words with facility, viz. about four or five years. Like chorea, it may be acquired by imitation; is almost always increased by agitation, or when it is remarked by others; and affects, for the most part, individuals who are endowed with a high degree of susceptibility. It may be frequently stopped by measured and regulated movements, as speaking slowly after a full inspiration, reciting or singing, in the same way as the irregular muscular action in chorea may often be suspended for a time by the patient's playing the piano, skipping, or performing other actions which require attention, and a regulated exertion of volition. Like other nervous affections, stammering is more common, and usually increases in intensity, about the period of puberty, and the succeeding years, when the mental sensibilities are so strongly called into play, but it diminishes towards the decline of life, and ceases altogether when the nervous sensibility is blunted by the approach of old age. When the stammerer is alone, or with an intimate friend or relation, he can usually speak very well, or at all events much better than when he is in company, or in the presence of strangers. This fact is not invalidated, but is rather corroborated, by the circumstances that some persons lose their stammer after a good dinner and wine, though in company; and that others, having began a speech on a subject which interests them, in a public assembly, have been able to go on speaking for a considerable time without any impediment; as in point of fact they are then in much the same

* Animal Magnetism and Homœopathy, with Notes illustrative of the Influence of the Mind on the Body. 2d Edition, 1838.

† Dictionnaire de Médecine, art. Balbutiement.

* Stammerers, when not attempting to speak, can, like other people, move their lips and tongue freely in all directions, except in those cases where the tongue is larger, or more bound down, than natural.

condition (with respect to the stammer) as when alone, having confidence in their powers, or forgetting their infirmity for the moment. It has been stated by a French author, that stammerers can generally speak very well when disguised by wearing a mask: and M. Itard mentions the case of a boy, eleven years old, "who was a great stammerer whenever he spoke in the presence of persons who looked at him; but he did not stammer when he knew that he could not be seen, and could speak to people very well when in the dark. The attempt had been made to cure him when he was younger by bandaging his eyes." These cases are obviously explicable upon the same principle. Most stammerers, again, are made much worse when put in a passion, though some, by being put in a passion, become extremely voluble, from their attention being altogether diverted to other matters. Stammering also resembles other nervous affections in presenting frequent intermissions at regular or irregular periods: some stammerers are affected by the state of the atmosphere, being frequently worse in wet than in dry, in warm than in cold weather. A few find their stammer better or worse according as the moon is in its first quarter or at the full. I have seen two persons in which this was the case. Some, again, lose their stammer for a few days, or even for a much longer period, after which it recurs without their being able to ascribe the recurrence to any particular cause; and as a further corroboration (if any be needed) that stammering is especially a nervous complaint, and of the view which I have expressed respecting its nature, I may allude to the fact, that the great majority of cases may be cured by systems of education which have for their object the regulation of respiration, and of the muscular powers concerned in speech.

Several persons, however, have attributed this complaint to various physical alterations of the tongue, fauces, tonsils, &c.; and, indeed, in a large proportion of stammerers some anormal or peculiar conditions may be perceived on examination of these parts; yet none of them are sufficiently constant to authorize the supposition, that the disorder is occasioned by them; though, no doubt,

when existing, they tend to aggravate it. In many individuals the tongue is thicker, its muscles being more developed than natural; in some it is more bound down to the floor of the mouth, either by the development of the genio-glossi muscles, or by the frenum being inserted too near the apex. In others, one side of the tongue (the right) is somewhat larger than the other, and the organ is drawn to one side on being protruded from the mouth. In several, again, the tonsils are swollen, and the arches of the soft palate are lower than natural; though, from what I have seen, I cannot concur in the opinion expressed by Mr. Yearsley, in his pamphlet, that, "in the great majority of stammerers, the tonsils and uvula are in a diseased state." On the contrary, I should say that, in many of the individuals who experience great difficulty in speaking, nothing anormal is perceptible in the appearance of the parts, and that the physical alteration most frequently met with is the increased size and more energetic contraction of the muscles of the tongue and beneath it, which sometimes prevent its being freely protruded from the mouth, or its tip from being turned over the lip towards the nose, notwithstanding the person's efforts, as would be the case with an individual whose tongue was swollen from the exhibition of mercury, or any other cause. This alteration I consider to be a consequence of the disordered nervous action, which, by inducing irregular and spasmodic contraction, causes a greater degree of development of the parts, as would be the case with any other muscular structure which is unduly exercised. We therefore see that there is more difficulty and spasmodic action induced by the attempts to articulate words which begin with some of the consonants than with the vowels, the former requiring more the concurrence of voluntary muscles than do the latter, the pronunciation of which is of a passive nature. We also see, in the majority of stammerers, that there is more difficulty in beginning a sentence or speech than in its continuation, as a more direct effort of volition is required to commence a muscular action than for its repetition; and many individuals can pronounce a difficult word with much greater ease if they are desired to repeat it after another person.

* Dictionnaire de Médecine, art. Bégaiement.

These physical alterations may, then, be considered as an accidental coincidence, or as an effect of the disorder. One or other of them are constantly met with in tolerably healthy persons, and others who do not stammer; and it must be obvious that if they were the cause, the effect must be permanent, and stammering would always be present, instead of presenting, as it does, such remarkable variations, which are occasioned by the state of the person's mind at different times, and by other circumstances to which I have alluded. The same may be said of the opinion which would refer the complaint to the the incident or reflex action on the spinal cord, to which of late years it has been the fashion to ascribe many diseases the origin of which is referrible to a higher source*.

I have, however, seen several individuals (though the number is small when compared with the others) in whom the physical alteration in the size of the tongue, and the energy of the contraction of the *genio-glossi* muscles, appeared to be the cause of the infirmity, from the manner in which the tongue is bound down, and the resistance which is afforded on attempting to introduce the fingers beneath it. This class of stammerers differs from the other, inasmuch as they do not stammer in general, but invariably upon the same words beginning with a consonant, as C, B, P, K, or T, or any combination of syllables resembling them: they are sometimes a minute or more before the difficult words can be articulated, after which they can go on pretty fluently, and they experience nearly as much

difficulty if the word be in the middle of a phrase as if it be at the commencement. They are not, like the generality of stammerers, affected by being in society, as they experience an equal difficulty when alone: neither are they influenced by change of weather, &c. The first individual with this kind of stammer, whom I noticed, was a man who presented himself at M. Amussat's, and who could not pronounce the word *courroyeur*, and two or three others which resemble it, but in other respects could articulate tolerably well. Immediately after the section of the *genio-glossi* muscles he could speak this word and the others without any difficulty; and when I saw him for the last time, three weeks after the operation, he had no further impediment in his speech. I have little doubt that several of those, whom a long treatment and education have failed to cure, would be found to belong to this class*. There is, again, another class of individuals in whom the nervous or general stammer (which is sometimes upon some words, and sometimes upon others, and to which the preceding remarks principally apply) is combined with the difficulty in articulating particular words; these persons, though not free from the stammer when alone, can yet speak much better, and are much less liable to gesticulations of the head, neck, or limbs, and to choreal or spasmodic action of the muscles of the face or lips, than when in company with strangers, or otherwise excited. In several of those whom I have seen, there has been nothing remarkable in the appearance of the tongue or mouth, though the majority of them cannot turn the tip of the tongue upwards over the lip, and the muscles of the organ contract forcibly on the introduction of the fingers beneath it. I am inclined to think that in these persons the difficulty in the articulation of particular words

* "The instant production of several nervous affections from moral impressions, the variability of the symptoms, their transient nature and periodicity in many cases, are incompatible with the existence of organic lesion as their cause; and, although there may be some unequal distribution in the capillary system of the brain or spinal cord in many instances, yet this is probably an effect. The immediate cause of the symptoms most likely consists in some modification of the nervous action, with which we are unacquainted."—*Treatise on some Nervous Disorders*, &c. p. 22.

"The frequent variation and the cessation and aggravation of the symptoms at regular or irregular periods, are features peculiar to disorder of the cerebral functions, serving, in many instances, to distinguish it from other diseases. These peculiarities may be accounted for by the constant succession of impressions to which the brain is exposed. The disorders of that organ do not consequently follow the definite course pursued by affections of other parts."—*Ibid*. p. 26.

* A well-marked case of this permanent or physical stammer occurred in a man who was a patient in the hospital Beaujon for a surgical disease. The tongue was bound down to the floor of the mouth by an extremely short frenum, which even turned its tip downwards. As soon as the membrane was divided, the patient, who previously could scarcely speak a few words in succession, spoke distinctly and without difficulty; but, as he did not take proper precautions against the part reuniting, he daily lost some of the advantages of the operation.—*Dict. de Méd. et Chir. pratiques*, art. Langue.

is superinduced upon the nervous stammer; and that, when in an aggravated form and of long duration, stammering would always be found to be connected with increased muscularity of the tongue.

[To be continued.]

CASES OF PTOSIS.—OPERATION.

To the Editor of the Medical Gazette.

SIR,

As the subject of ptosis appears just now to attract a little attention, I take the liberty of furnishing the two following cases from my note book:—

Samuel Jepson, æt. 30, applied on Nov. 28th, 1840, with ptosis of the left eye. Four years ago, after unusual exposure to cold, on waking from sleep, he found that he had lost the power of elevating the upper lid of the left eye. At the present time, the space between the lids is in extent about a fourth of that on the opposite side; there is no voluntary power of raising the upper lid, which feels soft and flaccid, and is not hypertrophied. The irides act equally, vision is perfect, and there is no palsy of any of the muscles of the globe.

A large elliptical fold, consisting of integument and a portion of the orbicular muscle, was carefully dissected away with the scalpel, the upper incision at its centre being close to the eyebrow. Four sutures were employed.

Dec. 10th.—A longitudinal raised seam marks the site of the portion removed.

30th.—There is now nothing disagreeable in the appearance of the eye, the most striking peculiarity arising from the absence of the natural fold beneath the eyebrow. The patient can close the eye perfectly; but, when winking, the upper lid is moved less, and the lower lid is elevated higher, than is the case with the right eye.

March 3d, 1841.—Sarah McCarthy, æt. 28, has ptosis of both eyes, which, from her own account, is congenital. She states that the lids could never be more separated by a voluntary effort than at present. The inter-palpebral aperture is about a fourth of the usual extent. To enable her to view surrounding objects, the head is thrown back,

and both corneæ so depressed as to produce, when the upper lids are raised by the fingers, the appearance of downward squint. Vision is perfect; irides active; and all the muscles of the eyeball can be thrown into action, although, from the constant accommodation of the corneæ to the aperture between the lids, the inferior recti seem to have acquired predominance. The appearance of the face is peculiar, from the total absence of palpebral folds in the upper lids, and the very marked corrugations of the forehead, and raising of the inner half of each eyebrow, which have resulted from the constant but vain attempt to open the eyes by the energetic action of the occipito-frontalis and corrugatores superciliorum. There is no hypertrophy of the lids.

A portion of the substance of the upper lid of the left eye, half an inch in width, and an inch and half in length, was included between two elliptical incisions, and dissected off from the subjacent conjunctiva. The middle of the upper incision, and its inner extremity, were close beneath the eyebrow. By means of four sutures and strips of adhesive silk, the cut edges were retained in perfect apposition.

March 10th.—As the wound had perfectly healed, and the patient no longer required the eye to be covered, a similar operation was performed on the right eye.

April 2nd.—The existence of a curvilinear seam, and the want of the natural fold in each upper lid, are all that would be noticed as peculiar. At the corneæ, the vertical space between the palpebræ is about half an inch, and can be slightly increased at will. In this, as in the preceding case, during closure of the eyes, the lower lids are more raised to meet the upper than before the operation, or than is natural in other persons; and, instead of the lids quite meeting in the common act of winking, the corneæ is revolved to a noticeable extent under the upper lid, and a portion of the white sclerotica remains visible*. The undue action of

* In his notes to Paley's Theology, Sir C. Bell ascribes the depression of the lower eyelid to the action of the levator palpebræ superioris, which, by slightly projecting the eyeball, causes it to push downwards the inferior palpebra. Independent of other arguments against this supposition, the greater degree of elevation, and con-

the inferior recti is almost lost, the corneæ being as nearly as possible in the centres. The throwing back of the head, previously necessary, is no longer marked.

In the *MEDICAL GAZETTE* of March 25th, Mr. T. B. Curling published some interesting cases, including one of ptosis from palsy of the third nerve, on which he operated on the same principle which guided me in the above cases, in January 1841.

From the original paper of Mr. Hunt, and Mackenzie's remarks, as well as from some conversation which I had with the former gentleman previously to my first case, it was my impression that the new method described by him (viz. that of substituting the action of the occipito-frontalis for that of the levator palpebræ) as succeeding in traumatic ptosis, was the best operation in every case of ptosis, from whatever cause, in which an operation was advisable at all. I was not aware at the time, that its performance had hitherto been restricted to the cases in which it had been first tried.

I am, sir,

Your obedient servant,

C. RADCLYFFE HALL.

Manchester, April 17th, 1841.

PLURALITY OF CHILDREN—THREE GIRLS AT A BIRTH.

(*For the London Medical Gazette.*)

CAROLINE CHURCH, æt. 35 years, the mother of eight children, came to London, from Hayes, to the burial of her brother-in-law, March 26th. On the Sunday afternoon, March 28th, she was taken unexpectedly in labour, when a midwife was sent for in great haste. She was delivered of a girl at half-past six o'clock, and of a second girl at a quarter after seven o'clock, without any apparent second rupture of membranes. As the placenta did not follow readily, Mrs. Moss, the midwife, passed up her hand to assist in its delivery. She felt another set of membranes whole, which she ruptured with some difficulty, as they were extremely tough, and deli-

vered a third girl, footling, at a quarter after nine o'clock, the children all living. The woman was extremely low and unconscious. A few minutes before eleven o'clock the placenta was withdrawn.

Monday, 29th.—At the request of the midwife I visited her.

The mother is a stout robust woman; her legs enormously swollen; abdomen large and tender.

The children moderate sized, healthy looking; the third, or last-born, the smallest.

The first presented the head.

The second, arm and head.

The third was delivered footling.

The placenta (which is in possession of Dr. Robert Lee) was in one mass, the uterine membranes being common to the whole. The first two children were apparently contained in the same bag or set of fetal membranes, that is, there was no apparent membranous septum between the two. The third had a very distinct, firm, membranous septum, with distinct chorion and amnion. One, the third or single child's placental umbilical cord was injected with wax, by which only a portion of the placental mass was filled, and without any communication with the remaining and largest portion: subsequently air was thrown in by a second umbilical cord, and a portion of the remaining mass only was inflated. Air was then thrown into the third umbilical cord with a similar result. Thus it would appear that, although the placenta was in one mass, there was no communication between the placental vessels of the three children: notwithstanding that two of them were contained in one bag, still each had its distinct portion of placenta.

Mrs. Church did very well for a fortnight, suckling the three children alternately, when, on Sunday, April 11, she had a severe attack of intestinal fever, from which, after a considerable struggle, she has perfectly recovered, but without the capability of again nursing her three children. They are now in average health, at 29, Harrow Road.

HENRY DAVIES,

18, Saville Row,
May 4, 1841.

sequently of subsequent depression, of the lower eyelid in these cases where the levator palpebræ is so inefficient, appear objections.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Socio, etc.; XAVIERIO LANDERER, Pharmac. Reg., Chemiæ Prof., Colleg. Med. Membro, Equite Crucis arg. Salvatoris, etc.; JOSEPHO SARTORI, Pharmacopœio Aulico. Athenis, ex Typographia Regia, 1837.

THERE lies before us a *Pharmacopœia*, published at Athens, by Royal authority, and with the approbation of the College of Medicine. The work is interesting in various points of view, and, certainly, in none more than in calling us back, after the lapse of ages, to that classical land which produced Hippocrates, and other sages in the healing art. Another interesting circumstance is, that, in giving the modern Greek names of the various medicines, it assists us in making out their ancient history; for, although Sibthorp effected this with respect to various plants, yet, for all the medicines more peculiarly so called, we know of no work, but the one before us, from which any considerable assistance can be derived.

From the account given in the Προλογος, it would appear that the present

undertaking was greatly wanted, owing to the confusion which had arisen in modern Greece from the number of medical men, who, having received their education at different European schools, adopted correspondingly different forms and modes of prescribing, giving rise, the editors inform us, to great confusion.

The Greek Pharmacopœia is divided into two parts: the first comprising those medicines which are supplied by the merchant, the second those made by the pharmacopolist; each of which has a description of the mode of its preparation. The whole work is also given in two languages, namely, Latin and modern Greek,—in this respect resembling the American Pharmacopœia, which is given in Latin and the vernacular tongue; while the plan of giving short descriptions of the substances used seems to be taken from that of Prussia, which it exactly resembles.

The names selected profess to be those best known, except with regard to chemicals, the names of which, we are told, are those most accordant with modern science. But, in neither respect, is the selection always happy: as we have *China fusca* and *regia* (from the Italian *Pharmacopœia*) for our *Cinchona Cordifolia* and *Lancifolia*; while the Sulphate of Quinine is designated *Chininum Sulphuricum*. Again, we find some of the old, and, in Europe, nearly exploded chemical designations adopted, such as *Ferrum muriaticum*, *Kali muriaticum oxygenatum*, &c.

Opium is represented as the product of two species of poppy, the *Papaver officinale* and the *P. somniferum*; but of these no more is said than that they are “*plantæ annuæ in Oriente et Ægypto cultæ*.” Do they refer to the two kinds of poppy mentioned by Hippocrates, the black and the white, and which are described by Dr. Royle as varieties only?

The name *Calumba* has led to the mistaken notion (not, however, confined to the Greek *Pharmacopœia*) that the root in question is brought from Columbo, in Ceylon; although we are rather inconsistently told, immediately after, that it grows at Mozambique!

The *Hellebori nigri radix* has afforded the Athenians an opportunity of falling into error; and we may remark, that

They are not the only parties to whom the same plant has proved a stumbling block. It is well known that Sibthorp satisfactorily proved the *ΕΑΛΕΒΟΡΟΣ ΜΕΛΑΣ* of Dioscorides to be the *Helleborus officinalis*. Now the London College seems to have imagined that this plant must therefore be the source of our black hellebore, although it is well known that our root is the *Helleborus niger*, and comes from Germany, not Greece. Accordingly, the authors of the Athenian Pharmacopœia, although they refer to the "*officinalis*," yet adopt the *Helleborus niger* of Switzerland and Germany as the medicinal plant; thus fully establishing the mistake of the London College.

Upon the whole, the work is one of interest, serving to shew the state of medical science in modern Greece; and, as such, we have thought it deserving of this short notice.

MEDICAL GAZETTE.

Friday, May 14, 1841.

"*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*"
CICERO.

THE MEDICAL SCHOOL EXAMINATIONS.

THE return of the time for the examinations in the several medical schools reminds us of the necessity of again urging that they should be made to serve those purposes in medical education for which they are so evidently well adapted. We do not deny that already they have done much good, and will continue to do it; that the energy shown by the students since their introduction has been greater than it was before, and has been shared by a much greater number; and that they have given rise, in all who have engaged in them, to an honourable feeling of emulation, which has led them to acquire a much wider and deeper knowledge of professional sci-

ences than otherwise they would have attained.

All this, and more, might be truly said of the benefits resulting from the school examinations, and yet they will not have accomplished nearly all the good of which they are capable till they are made compulsory, universal, and necessary as a step previous to admission to the examination for the diploma. For, at present, their advantages are usually limited to a comparatively small proportion of the students of each class. When we look over the lists of the successful candidates in this and in past years, we find that they include but few names, and that very evidently the greater number of the students of each school have not engaged in the competitions at all. We do not mean to imply by this, that the credit of those who have gained prizes is much less than it appears, or that they have not fairly beaten the whole of the classes of which they are severally members; on the contrary, the probability is, that in general they have been suspected throughout the season to be the best men, and that therefore only a few have ventured to compete with them. But still their honour would have been greater had they occupied the same places after a fair competition with the whole class; and the rest, if they had had the stimulus of necessity to make them compete, would not have been so far behind as now they are.

There are, we suspect, very few among the medical students who, if they were compelled to a competition, would not do their best, and strain every energy, to occupy a respectable place in the examinations. At present many think it better to be safe against having a low place than to take their chance of getting a high one; and they refrain altogether from the contest, content with an average reputation for industry and attainments; but if the

examinations were universal this would cease, and there could be no safety from a low and somewhat disreputable position, except by the steady pursuit of knowledge. It seems certain, therefore, that such a plan as we propose would have the immediate effect of increasing many-fold the amount of work done in the medical schools, and of raising the average standard of acquirement among the pupils.

But besides this (in itself sufficient to render the question most worthy of consideration), the school-examinations, if all the students were compelled to pass them, might be made to remedy a great number of the defects which now confessedly exist in the scheme of medical education. For what purpose, for example, is all the difficult and tedious system of registration adopted? registration of lectures entered to, and of lectures professedly attended, and of residence in London, and so forth. It is said, to insure that the student regularly and diligently pursues a proper course of studies. And all this would be very well if the system accomplished any fair proportion of what it pretends to; but it is notorious that all that the most scrupulous registration can determine is, that the student entered at a certain time upon the right to attend certain lectures, and that, at certain subsequent periods, he was residing in London; but whether he attended his lectures regularly or not is always a matter of doubt; and whether he learnt any thing from them—whether he slept through them, or listened attentively and studied them at home—is never enquired into, although it is obvious that this is the only question the answer to which would be really important. Now the whole system of registration might be safely dispensed with, if at fixed times during the course of their studies all the medical pupils were

made to pass examinations in ^{ing} several subjects on which they ⁱⁿ attended lectures; and if, ^{his} when ^{of} the ^{blo} results of such examinations were ^{ed} not satisfactory, they were stayed in their course and held back to learn the necessary elements of medicine before they proceeded (as they now often do, unprepared and unfitly) to the study of its higher branches.

The greatest and hitherto the most insuperable evil which has resisted the benefits of every scheme of medical education is, that some of the students, after spending the greatest part of their time for their own amusement, and learning therein absolutely nothing of their profession, have yet been able to pass the ordeal of their examinations by a few months' artificial and comparatively useless study. The system of *grinding* has undoubtedly attained in these times a degree of perfection, which, as far as we know, in no other studies than those of medicine, it ever even aspired to; and it now almost defies examinations to detect the superficiality and inutility of the knowledge which it gives for the day of trial, but which vanishes in the following month, and leaves the intellect as dull and empty as it was before the system was commenced. We do not say that the necessity of passing school-examinations would altogether put an end to this baneful system; but we are certain that it would be to it both a heavy blow and a great discouragement. For the school-examinations the students would seek the assistance, not of grinders, but of their legitimate teachers, who could best and most cheaply instruct them in their own lectures—the subjects on which exclusively they would be examined. At present the evil is, that a pupil, having mispent a large portion of his time, cannot go to his legitimate teacher to ask him to repair the loss

by extra and daily instruction; and, therefore, putting off to a continually later period the time of study, at the last hour, and only when it is absolutely necessary to do something, does he adopt an illegitimate and useless mode of study. With repeated (say annual) school-examinations, this must in great measure cease; or even if they did not altogether abolish such a system, they would still be greatly beneficial; for, at the least, they would compel the student to be capable of passing examinations several times instead of once in the course of his study, and would give him by so many times a better chance of learning something of his profession, even in spite of himself.

Another evil that would be remedied by this measure is that to which we lately alluded as rendering desirable a system of more intimate *personal* instruction of the pupils; namely, the difficulty which they find in the earlier part, and sometimes even through the whole course of their education, in determining how and to what they shall give their chief attention. We are convinced that on this the loss of a great amount of most valuable time depends; and that the defective state of knowledge in which many students at last find themselves, depends on their not having studied aright, either in mode or order, much more than on any incapacity to learn what ought to be definitely set before them. At present, a pupil coming to London is given to understand, in few words, that in three years' time he must attend so many lectures on so many subjects, and so many days hospital practice, both medical and surgical; and that at the end of that time he must pass two examinations, which will include a great number of subjects which have no very evident connection with each other, but which extend from Botany to Practical Surgery. Well! with an in-

definite idea that the things would not be given to him to do, if they were not possible to be done, he sets to work, and takes the subjects that the Worshipful Society of Apothecaries have declared shall be learned in the first seven months; namely, anatomy, chemistry, materia medica, and (as added by the College of Surgeons) surgery. The result of the endeavour to study all these is always bad; but what form of mischievousness it will assume, depends much on the particular disposition of the student. If he be a young man of humility, and distrustful of his powers, he soon finds himself utterly lost; instead of learning all, he can learn not one of his subjects: he has neither time nor talent for the study of one-half of what is put before him: and believing (what is very true) that it would require the intellect of a well-instructed old philosopher to do any thing creditable in four such subjects within the brief period of seven months, he either gives up the whole matter in despair, and takes to his amusements, or (if he be possessed of more than ordinary discernment) he suspects that the curriculum is only intended to make an appearance of learning—he drops half his subjects—and, giving all his attention to those he likes best, or thinks most important, he leaves the remainder till he wants a knowledge of them for his examinations. And this last is a very wise course of proceeding, and the one which we very generally recommend students to adopt. A much more mischievous one is that pursued by most of the students, who, instead of this humility, possess a good opinion of their own powers of acquiring knowledge. Such an one is sure to find reason for believing that he makes progress, and satisfactory progress too, in all his studies, and he passes without ruffling himself through all the intricacies and difficulties of the curricu-

lum; and if his progress were all real and sure, he would indeed be a very perfect example of what medical education-systems seem to imagine medical students to be: but there is too often a melancholy end to all this. The examination at last comes, and with it, for the first time, dissatisfaction: the knowledge is found to be utterly superficial and useless, and the condition of him who had studied every thing is inferior to that of him who had left half his subjects uncared for. Now, in this respect, for all classes of pupils, but for this last more especially, who constitute a very considerable number, the system of frequent examination would be most beneficial.

Against such a system we are not aware that any good reason could be urged. It may be said to be troublesome; but the time is gone by when the trouble could be made an excuse for not undertaking what would be beneficial.

There is indeed another objection, but it is only apparently one, against this system. It is that it is absurd to expect the average of students to learn even a little of the subjects set before them in each, and especially in the first, season. This is quite true—it is absurd: not one student in a hundred learns a moderate quantity of each of his subjects; but this is not because of examinations, nor would the evil be increased by them. It is the result of the absurd mode in which the curriculum of education is arranged, and to which we shall take an early opportunity of alluding.

VACCINATION AMENDMENT BILL.

IN this bill it is proposed to enact—

1. That it shall be and be deemed to have been lawful for the Guardians of every Parish or Union in England by whom the contracts for vaccination may respectively be or have been made

under the provisions of the act 3 and 4 Victoria, c. 29, to defray the expenses incidental to the execution of the said act out of any rates or monies which may come or may have come into their hands respectively for the relief of the poor.

2. That the vaccination, or surgical or medical assistance incident to the vaccination, of any person resident in any Parish or Union, or of any of his family under the said act, shall not be considered to be parochial relief, alms, or charitable allowance to such persons; and that no such persons shall by reason of such vaccination or assistance be deprived of any right or privilege, or be subject to any disability or disqualification whatever.

MEDICAL REFORM.

To the Editor of the Medical Gazette.

SIR,

ONE of the greatest difficulties connected with the arrangement of medical reform, is the constituting an order of practitioners for the service of the middle classes of society. It was proved, before the parliamentary committee, that so far from it being possible to effect this object by lowering the qualifications of such practitioners, they are precisely the persons in whom professional skill, liberal education, and moral principle, are most indispensable; since the opportunities of abusing their trust are numerous, and those who avail themselves of their assistance have not the means of obtaining consultations. The rich have those means; and the "poor" are without pride, and procure, on charitable grounds, due professional aid*. The proverb "*medio tutissimus ibis*" is quite inverted, when we compare rank, with the opportunity of obtaining adequate medical assistance; for practitioners, qualified as above mentioned, will certainly not devote themselves to hard work, and low remuneration, without the opportunity of either acquiring character, or the satisfaction of having performed a charitable act.

* It is quite a mistake to suppose that the class termed "the poor," are really the most deserving of commiseration. Take, for instance, the case of a widow, formerly well to pass in the world, but now in limited circumstances, requiring good (the best) medical assistance for herself, or one of her family: or that of a half-pay officer, whose wife suffers from a preternatural accouchement.

There is certainly no ground, established either on reason, common sense, political economy, or Christian feeling, why the middle classes should be thus treated. They are our countrymen, fellow tax-payers, persons of political influence, and brother-Christians. Their health and lives are surely as valuable as the "liberties" of the West India negroes; and their preservation of as much importance to Great Britain as the emancipation of our sable dependents, procured at the cost of twenty millions of money. Why, then, should not the interest of such a sum, if necessary, be deroted for the former purpose?

To be brief, I propose that the United Kingdom shall be divided into districts, and placed under the medical superintendence of a staff composed of competent physicians, surgeons, and pharmaceutical chemists, so as to afford a degree of professional aid to the middle classes of society, and take them out of the hands of quacks, nostrum venders, ignoramuses, and dealers in medicine by quantity instead of quality. The staff ought of course to be constituted, as in the army, of various grades; the juniors having the most work and least pay, and seniors promoted, on merit to the more responsible stations. Each officer ought to receive a salary, on a scale perhaps like that in the army, and be strictly superintended in the performance of his duty.

It is certainly not an easy matter to provide against the abuse of measures calculated for the public good; still, by proper surveillance, under the guidance of clerical and other parochial officers, means might readily be adopted to prevent any but the really deserving obtaining relief, according to the system above mentioned. Every claimant ought to be required to contribute, according to his or her ascertained means, to the aggregate fund, which must, of course, be aided by a large parliamentary grant.

Some of your readers may, perhaps, object to the plan, on the grounds that it would not be consented to by the authorities. Where, however, the principle is in itself right—where the only objection is an increase of taxation, to be borne chiefly by those about to derive benefit from the measure, and where this party is possessed of great political influence—I do not anticipate much difficulty as to the plan being carried into execution, if properly urged.

I am, sir,

Your obedient servant,
A PROFESSOR IN THE SCHOOL OF
PHYSIC IN IRELAND.

THE SHOP AND APPRENTICESHIP SYSTEM.

To the Editor of the Medical Gazette.

SIR,

I SHOULD feel infinitely obliged by your admitting into your valuable pages a few observations upon a point of medical reform, which seems, in the majority of cases, to be overlooked, or only slightly glanced at. I allude to the conjunction of pharmacy with medical practice, and the truly ridiculous and degrading custom of regulating charges by the amount of medicines supplied. These are the two great and flagrant evils laboured under by general practitioners, and involve others of scarcely less importance. In most schemes of medical reform, the great demand is, a change in our political condition, and a greater amount of professional equality; that this would be a source of happiness to some few I readily admit, but believe that the great majority would be far more content with that change in their condition which should tend to elevate them in the public eye, and generate within their bosoms that pride in their profession and brethren which is one of the most certain sources of self-esteem.

But to a detail of the evils. In all other departments of civilized life, the division of labour has kept pace with increasing civilization and refinement, but it was reserved for the nineteenth century and enlightened England to continue, or rather introduce the system, repudiated by the rest of Europe, of imposing upon the same individual the highly intellectual task of discriminating and treating disease on the one hand, and on the other, of watching boiling pots, and rubbing up pills, or exercising their taste in the selection of variously coloured papers with which to cap their bottles.

The worst consequences of this unhappy conjunction are the shop system, the apprenticeship system, and the useless occupation of time.

The shop system is pregnant with evil to the individual, to the profession, and the public.

The first effect upon the mind of the individual engaged in retail, is "decrease of self-estimation." The man who practises his profession in this manner will soon be convinced, in spite of any feelings with which he may have commenced life, that he is but a tradesman, and regarded in such light by the petty shopkeepers around.

For some time he may with proper spirit struggle against this humiliating position, and endeavour to maintain an air and manner of superiority; but what is the con-

sequence? the good people, finding that he shuns familiarity, or declines the gossip in which they are disposed to indulge when patronizing his house for a pennyworth of salts, at once proclaim him as a proud man, and infest their richer neighbours with the same notion, who, naturally enough, shun intercourse with one who sets himself above his station. Such, unfortunately, is generally our pecuniary condition, that, finding this independent and strictly correct conduct causes the loss of practice, we are compelled to bow the knee, and fall into the habits and customs which are most agreeable to those around; use shortly begets a second nature, and in due time the educated and scientific surgeon may be seen standing at his shop door, with hands behind his apron, cracking jokes with the milkmaid, or hand in glove with some neighbouring Boniface. What is the deplorable result? In a short time he sinks down to the mere vegetative being—eats, drinks, and is happy. But this degradation is not confined to himself; in his fall, he drags down with him the whole profession. It is this unfortunate abuse which makes us rank beneath every other profession, and induces young men of spirit and gentlemanly feeling to enter the army, navy, and East India Company's service, where, although the remuneration is limited, they can possess the feeling of pride in their occupation and associates.

These, sir, are plain and painful truths. The Queen's commissioner, the clerical and legal gowns, are universal passports to society. But, for ourselves, our profession is rather detrimental; we only obtain admission through tolerance or individual respect. This is not visionary. I would quote a recent circumstance of medical exclusion at Naples from your own pages, and a similar affront which was put some time ago (unintentionally it was said) upon the medical officers of one of the regiments of Foot Guards within my own knowledge. An English physician applied for introduction at one of the small German courts, and received for reply, that he would be willingly permitted to show himself, on condition that he would drop the title "Doctor," and merely appear as a private gentleman. I shall be told in reply, "This is puerile, and unworthy of thought by philosophic minds;" but such are few in number, and those even that exist, are rarely above courting the good opinion and respect of their fellow-creatures. An important question, however, occurs here: what is to become, in case of any peremptory legislative enactment, of those who now only continue to attain a scanty sustenance by means of retail? This is, indeed, of consequence, and brings to our view the evils of an over-stocked medical market.

This apparent comparative facility of gaining an existence is a great and fatal encouragement to parents, when debating upon the choice of a profession, to select our own. Oh! say they, why should we make our son a tradesman? when, by a very little additional outlay in premium, we can make a gentleman of him, being comparatively ignorant of the subsequent demands upon their purse. He is thus cast upon the world without being able to wait, in the regular course of practice, for an income; in self-defence takes to retail; and thus from day to day is the evil perpetrated. It is an invidious proposal that intellect should be kept down by pecuniary barriers; but surely that is a less evil than that a whole profession should be lowered in the social scale, and driven to all kinds of internal meanness and dissension by their rivalries. What is the cause of those pitiful endeavours to supplant one another, so often displayed? Superfluity. Why is it that men not unfrequently sacrifice honour, conscience, and their patient's welfare, to their own aggrandizement? Why, from our superfluity. A man, whom it was once my misfortune to know, used to inculcate such maxims as these: "the times are scrambling ones, if you ever get a good patient, strike it in [meaning the medicine] as much as you can, and make the most of him." There, sir, was a specimen of a medical philosopher.

Again, our mutual ill-will, and malevolent and depreciating observations, are proverbial. And is not the public injured by such proceedings? Undoubtedly; the man, whose mind is all day dwelling upon drugs, is surely not in a condition to be an improving practitioner; his time is too much occupied by considerations of profit and loss, the price-current of drugs, the appearance of his shop window, and the brightness of his bottles, to give much thought to the science he professes. Anxious as I am, to see every member of our profession possess a voice in the election, and the chance of a seat in the councils of its governing bodies, still I would by no means consent to such a change until its lowest members, the present retailers, had given up their trade, and could appear with proper dignity in such situations. Until such be the case, I am well content with those who stand forward as our leaders; men, whose birth, education, and connection, enable them to move in the first ranks of society. The class of physicians, as now constituted, is invaluable in giving tone and respectability to the profession. The enemies of the College say, "it is too exclusive; it denies its highest honours to almost all but University graduates." Well, be it so; I maintain that any one complying with its regulations, by giving himself a first-rate

education, more fully entitles himself to an easy access to its high places, than any one who devotes himself exclusively to medical pursuits; indeed, I have pretty universally found a man's professional information bear a direct ratio to his general acquirements.

It is, indeed, laughable to hear the occasional self-sufficient observation of some medical *parvenus* in asserting, that the general practitioner is a much better informed man than the physician, because he divides his attention amongst a greater variety of subjects, whilst the former concentrates his upon one. Another evil, the very name of which smells of the trading source whence it is derived, is the system of the apprenticeship; and this, too, is the unhappy consequence of blending pharmacy with practice. In the most desirable cases, the unfortunate youth spends two or three years more than necessity requires in pure dispensing, which can for all practical purposes, be acquired as well in twelve months as twelve years. Instead of being truly a pupil, and benefiting by his master's knowledge, he is too often taken only to save the expense of an assistant, and made a domestic drudge. Is it wonderful, that such a course of discipline should stifle all just and gentlemanly feelings?

The last circumstance to which I shall direct your attention, is the custom of regulating charges by the amount of medicine supplied. Of all professional absurdities it is the worst. It leads in every case to what has been happily termed the "drenching system," giving the unprincipled practitioner an opportunity of increasing his gains at the expense of the patient's health—certainly of his comfort, and depriving the honourable one of just remuneration. It is, besides, a fiction of so truly ludicrous a character to suppose or impress upon the public mind the fact, that we claim recompense only for drugs given, and not for the exertion of mind or manual skill, and which has led to the vulgar aphorism that we get eleven pence halfpenny out of a shilling. It leads also to another intolerable annoyance; I mean occasional requests that something should be deducted from the sum total of a bill, as they think the charges much too high, and wonder how they could have wanted so many draughts per day; and this request is, I regret to say, not unfrequently complied with, in order that the practitioner may retain his patients, thus tacitly acknowledging overcharge. For all these great and constantly recurring annoyances, I believe the separation of pharmacy from medicine would afford a certain remedy; and I cannot imagine a single valid argument in favour of its continuance. It would at once abolish shops and apprenticeship, and compel us all to regulate our at-

tendance by a certain known scale of fees, the amount of which might be determined by the age and professional standing of the practitioner.

The first five years of practice might entitle him to half a crown a visit; the second five, to five shillings; and all subsequent times to seven. These should be the maximum; but, doubtless, in many cases, charitable feelings would induce him to diminish the amount. Although I would most willingly see these paid at the time, yet I believe such would be an extreme inconvenience to the middle classes, when salaries are received at certain periods of the year; yet, I would have it distinctly understood, that the account should be sent in upon the termination of the illness, not waiting until Christmas, and then following in the wake of the bootmaker or tailor. But it is not sufficient to wait until we ourselves or the public adopt these measures spontaneously: they must be made the subject of legislative interference, otherwise they will never take place, for any one attempting innovation is regarded with a very jealous eye. These are the reforms which will be most efficient in brightening the prospects of the profession, and rendering the labour one of greater sweetness. I have not dwelt here upon the imprudent pretensions of the chemist; for I feel satisfied that, did we give up dispensing, he would readily abandon so dangerous an occupation as playing with the edge-tools of medical practice. With many apologies for my prolixity,

I am sir,

Yours respectfully,

J. R. B.

ON CONGENITAL OPACITY OF THE CORNEA.

To the Editor of the Medical Gazette.

SIR,

IN your journal for April 30, Mr. John Christie, of Glasgow, has obliged your readers with an interesting communication "on congenital opacity of the cornea." In the course of that communication the following statement occurs:—"Mr. Middlemore, of Birmingham, it would appear, doubts the occurrence of congenital opacity of the cornea; but the cases now on record, although few in number, leave no question as to the possibility of such an event; and the veracity of Messrs. Crompton, Walker, and Barton, cannot be called in question, however it may run counter to the preconceived notions of Mr. Middlemore." As my opinions, on this occasion, are greatly misrepresented, I can only suppose that the author, not having

seen my treatise, has relied, for his information, on a quotation from it, given by Mr. Crompton, of Manchester, in a former number of the Gazette, which is quite too partial and incomplete to convey a correct notion of my views. In truth, I have never doubted the existence of congenital opacity of the cornea (in fact, I have seen it in several instances), either as a consequence of hydrophthalmia, of imperfect development of the cornea, or as a result of inflammatory intra-uterine disease. I have never attempted to throw any doubt on the "veracity" of Messrs. Barton, Walker, and Crompton, for I have not replied, in any public form, to their statements; much less offensively, or with a view to impeach their veracity. I had no "preconceived notions" on the subject, but have merely arrived at a conclusion after a candid and attentive investigation of evidence.

Some years ago, when engaged in arranging for publication my treatise on Diseases of the Eye, I met with a statement in one of the old medical journals which much surprised me, and conceiving that the conclusions of the writer (which went to the establishment of a somewhat novel and highly important fact in ophthalmic pathology) were not borne out by the cases on which such conclusions were founded, I ventured to give an opinion to that effect. I have yet to learn that, in adopting this proceeding, I have deviated from the ordinary mode—the perfectly justifiable method—of examining the opinions of preceding and contemporary writers. In order that my professional brethren may judge how far I have merited the bland censures pronounced on me by Messrs. Crompton and Christie, I will connect with this brief communication the statement of Mr. Farar, and also my published opinions thereon, which have given so much offence to those gallant protectors of his fame. "About nine years since I was desired to see a child who was about a month old, and apparently blind, having the cornea of both eyes opaque, so that not the least of the iris was to be seen. My opinion was, that nothing could be done in this case, and that the child would for ever be blind. About three years after another child was born of the same parents, with exactly the same appearance. The manner in which the cornea acquired the transparency was, in these cases, remarkably curious. The external edge growing thin, soon after became clear and transparent; and after this the whole surface of the cornea brightened up, the centre being the last spot that recovered its transparency*." In reference to these cases

and the opinions and conclusions connected with them, I have said, "The occurrence of extensive opacity of the cornea, as an effect of purulent ophthalmia of newly-born infants, appears to have led Mr. Farar into a very curious blunder. In a paper read before the Society for promoting Medical Knowledge, he has very singularly pointed out as a congenital disease what I conceive to have been a mere effect of inflammation*." Because, sir, I have thus noticed the opinions (after having fairly quoted them) of Mr. Farar, on the subject of congenital opacity of the cornea, Mr. Christie has affirmed that I entertained preconceived notions on the subject of that disease, and that I have absolutely denied its existence! If the gentlemen who have taken the trouble to associate my name with opinions I never entertained will be so good as to wait a short time, they will find, in the new edition of my book, now in course of preparation, that I have ventured to speak more positively and definitely than I had hitherto done, in regard to the cases related by Mr. Farar, and their competence to sustain the conclusions since founded on them, although I have not neglected to give every attention to the cases and arguments adduced in their support by those whose knowledge has been assisted and guided by the published experience of many who have preceded them in the course of inquiry.

I am, sir,

Your obedient servant,

R. MIDDLEMORE,

Surgeon to the Birmingham Eye Infirmary.

COMPOUND CATHETER.

To the Editor of the Medical Gazette.

SIR,

I RECOLLECT Dr. Andrew Buchanan, of Glasgow, showing me, along with some other students, in 1832, his compound catheter, which I have seen him employ subsequently with considerable success.

When I read, in the part of your journal for last January, Mr. Foulkes' account of his instrument, respect for an old teacher caused me to think of claiming priority of invention for Dr. B. His letter of the 15th of February, however, superseded the necessity of any notice of the matter on my part. But on reading to-day Mr. Foulkes' second communication, which appears in this monthly part of the GAZETTE, I can neither refrain from publicly adding, along with "Sum

old, possessing an opaque cornea, would "for ever be blind." Neither would he have stated that the fact of an opacity of the cornea becoming thin at its circumference, before it disappeared at its centre, was "remarkably curious."

* See my Treatise on Diseases of the Eye, vol. i. p. 156.

* See Medical Communications, vol. ii. p. 463. The readers of the MED. GAZETTE will not fail to remark that a surgeon, possessing much experience in ophthalmic diseases, would scarcely have felt himself at liberty to say that a child, a month

Cuique," my testimony to the originality of Dr. B.'s invention, nor from expressing my sincere regret at the manner in which Mr. John Croxton Foulkes has penned his last letter. It is a very great pity that such a spirit as he evinces should have any existence among the members of our liberal profession. The injury which such an animus does to the advancement of medicine is incalculable, not to speak of its otherwise censurable character.

If Mr. J. C. Foulkes really did not get a notion of the instrument from the itinerant "catheter-maker," I am sure the readers of the *MEDICAL GAZETTE* will agree with me in thinking that he would be vastly benefited from *imitating* the very gentlemanly and courteous style of Dr. Buchanan. Besides ascribing, in a very unjustifiable manner, *motives* to Dr. B., Mr. F. charges him with selfishness in not making his invention known to the profession. The liberal and scientific character of the Doctor is too well known and appreciated to require my pen to defend it from such invidious attacks. His silence will be attributed by every one acquainted with him to the proper cause—his peculiar diffidence and unwillingness to appear before the public. In conclusion I would remark, that the "compound catheter" has been well known not only in Glasgow for the last ten years, but throughout Scotia, whose sons, I trust, will always feel proud of their illustrious "fore-runners" in medicine, in whose steps so many are still treading, and pushing onwards in the science and practice of their profession; and whose labours and attainments can suffer no tarnish when placed in comparison with that of their contemporaries of whatever country or clime.

Soliciting an early insertion of the above remarks,—I remain, sir,

Your obedient servant,

JOSEPH BELL, Surgeon.

Barrhead, May 5, 1841.

SELECT SURGICAL CASES.

Reported by GORDON BUCK, M.D.,

Surgeon of the New York Hospital.

[Concluded from page 158.]

Immobility of the lower jaw; division of the masseter muscle of the right side.

JOHN BISHOP, seaman, aged 19, born in Georgetown, D.C. About eighteen months before his admission to the New York Hospital, he had an attack of fever at the south, during which he was profusely salivated, and sloughing of the right cheek had occurred, with loss of considerable portions of the soft parts from the inside of the mouth. On re-

covery, he was unable to open his mouth, a band having formed, by which the jaws were kept firmly applied to each other. Unsuccessful attempts had been made to relieve this condition by dividing the constricting band, but without using means, at the same time, to force the jaws apart. Two portions of bone had been discharged.

On the 19th of August, 1839, when an operation was performed for the purpose of restoring the functions of the lower jaw, the parts presented the following appearances:

The right cheek was full and swollen, the skin and subcutaneous cellular tissue supple and moveable upon the masseter muscle, which could be felt contracting under the hand whenever he put it in action. In a state of rest this muscle felt hard and tense. On the inside of the cheek, a firm callous band extended from above the interval between the first and second upper molar teeth on the outside, to below the first molar tooth of the lower jaw, with a sharp unyielding edge, that would not permit the end of the finger to be insinuated between it and the outer surface of the teeth. The jaw was susceptible of a sliding motion, showing that the right tempora-maxillary articulation was moveable. The upper dental arch stood a little in advance of the lower, barely allowing the blade of a table knife to be introduced between them. His voice was very little affected. He was able to take solid food by cutting it very fine, and insinuating it between the upper and lower teeth. His general health was pretty good, and he had observed no change in the condition of his jaw for a year past.

Operation.—A bandage of two fingers' breadth, and sixteen inches in length, was insinuated between the upper and lower teeth, and the ends tied so as to form a loop below the chin. One assistant held the head firmly, while another acted on the lower jaw, by means of the bandage, bearing down so as to put the band to be divided as much on the stretch as possible. The fore-finger of the left hand was then introduced under the cheek, and the operation proceeded with, care being taken to avoid cutting near the middle of the masseter muscle, in order not to involve the parotid duct. Successive incisions from within outwards, and advancing from before backwards, guided by the sense of touch alone, were made on a level with the lower molar teeth, until the finger arrived at the last tooth; resisting bands were felt still farther back and were divided. By repeated attempts with instruments that acted as levers in prying the teeth apart, sufficient space was obtained to introduce the speculum oris, which acted with great effect in rupturing the fibres which still bound the jaws together. Proceeding cautiously, in this manner, alternately prying and dividing the

resisting bands, the jaws were separated so as to allow two fingers to be placed edgewise between the incisor teeth. The whole width of the masseter muscle was involved in the incision, and in some parts its whole thickness; the knife grating as if cutting through cartilage; the hæmorrhage was moderate, and ceased spontaneously. After the operation, the patient could himself open his mouth to the extent to which the teeth had been separated. A denuded bony surface was felt on the outside, a little behind the last molar tooth, and could be traced upwards to a rough pointed extremity, which was somewhat moveable. A wooden wedge was introduced between the molar teeth of the opposite side, and required to be kept in as much of the time as it was possible for him to bear it. Considerable swelling and inflammation succeeded the following day, and continued for some time. The use of the wedge was persevered in.

September 9th.—He could chew all kinds of food, and separate his teeth nearly an inch apart; with the wedge they could be separated still farther. The wound on the inside of the cheek is nearly healed; there is evidently a tendency to a reproduction of the same condition. A band is felt at the edge of the masseter when the parts are put on the stretch, resisting the farther separation of the jaws. He is himself sensible of their contracting. Introduced the speculum, and stretched the parts, and then substituted a thicker wedge, to be kept in as much as possible.

October 1st.—For a few days past the patient has used the speculum several times daily, for the purpose of stretching the parts which have still a great tendency to contract, and it produced a very good effect. By way of experiment, the jaws were left to themselves for twenty-four hours, when it was found that the thumb could scarcely be introduced edgewise between the teeth.

November 6th.—Since the last report the same treatment has been continued. Some of the newly formed bands have been divided. The patient has himself removed a portion of bone, which proved to be the extremity of the coracoid process, about three-fourths of an inch in length; he is now employed as nurse, and is left to use the speculum at discretion.

March 31st, 1840.—For several weeks past he has entirely discontinued the use of the speculum, and the parts have been left to themselves; his condition is as follows. The right cheek is much less swollen than it was before the operation, and is soft and supple; the masseter muscle feels hard. The forefinger can be introduced edgewise between the incisor teeth, and within these limits he has free use of the jaw, and perceives no tendency to farther contraction. The callous

band on the inside of the cheek exists very much in the same condition as before the operation, excepting that it does not advance as far forward.

May 30th.—He continues to enjoy the same use of the jaw as at the last report. A loose portion of bone is felt opposite to the upper molar teeth, and will require to be removed.

Enlargement of the bursa in front of the patella.—Cured by rupturing it.

Thomas Cranmer, of New Jersey, a seaman, aged 26, was admitted April 11th, with an enlargement of the bursa in front of the patella, caused by an injury about ten days previous. The tumor was of a globular form, and nearly half as large as the patient's fist.

It was seized firmly between the fingers, and pressed with great force, until it burst and discharged its contents into the cellular tissue beneath the skin. A roller was then applied, and the limb kept at rest for a few days. The patient was discharged cured on the 16th of April.

REMARKS.—Tumors of this sort are occasionally difficult to manage, and patients will not generally submit to have them broken by a direct blow. I treated a case precisely similar to the present, about a year previous, by tapping and injecting it with a solution of sulphate of zinc, as in the operation for hydrocele. In a few days after this operation, the tumor was again distended with serum as large as before, and continued so, until I finally treated it, as above described, by pressure until it burst, and with instant and permanent success. The enlarged bursæ occurring about the wrist, and occasionally under the chin, are more readily managed in this way than by any other means.

The other cases that called for operations, all terminated successfully: they present no points of special interest.

Opium mixed with superacetate of lead, in large dose, swallowed with impunity.

A seaman under treatment for a carious ulcer, near the lower part of the thigh, was seized with slight erysipelatous inflammation around the surface of the sore, for which the house-surgeon prescribed an opiate lotion, to be made from thirty grains of opium, and sixteen grains of sugar of lead. The patient, mistaking the directions, swallowed these substances in their dry state, about 8 o'clock in the evening of Jan. 26th. About midnight he began to feel unwell, and thinks he threw up a part of the powder; but he did not rest well during the night; no symptoms of narcotism followed the accident: on the following morning he was as comfortable as usual, and unaware that anything had gone amiss.

Is it possible that the superacetate of lead, which is known to precipitate the extractive matter of vegetable infusions, could in this case have had any effect as an antidote? The opium was good, and the patient had not been in the habit of using this substance.

An instance somewhat similar happened in the New York Hospital in the summer of 1837. A patient swallowed, by mistake, a drachm of opium mixed with a scruple of the superacetate of lead. The accident was discovered in about half an hour: an emetic was administered, and no serious consequences ensued.

ANCIENT MEDICAL STUDIES AT CAMBRIDGE.

THE ancient statute (*Stat. Ant.* 119.) prescribing the course of medical studies and exercises in this university, presents a very singular picture of the state of medical knowledge in those days. It made it generally necessary for a student to have graduated and *read* in arts, and to have subsequently, during a period of five years, heard *once* in the schools of his faculty, the book of Johannicius Philaretus *de pulsibus*, Theophilus *de urinis*, the Antidotarium of Nicholaus, with some one of the books of Isaac (Israelita), whether *de urinis*, *de febris*, *de dietis particularibus*, or *de viatico*; he was required also to have heard *twice* the works of Galen, with their glosses or comments (known only by their Latin translations from the Arabic, as the works of Tegnus Galienus), including his book of *prognostics*, of *aphorisms*, and *de regimine acutorum*; it was further required that he himself should read *cursorie*, within not less than three years of his *readings* in arts, (*Stat. Ant.* 90) at least one book on the theory and another on the practice of medicine; that he should have both opposed and responded in the schools of his faculty, and should have practised at least during one year: he was then admitted to his degree after the usual deposition and forms.

It is added, as an additional provision to the same statute, that no one shall be admitted *ad incipiendum in medicinâ*, unless he had practised medicine at least two years, a condition apparently inconsistent with that which is contained in the body of the statute, though it is very possible one might refer that to the degree of bachelor, and the other to that of doctor in medicine. If a person had not exercised the functions of a regent in arts, he was required to have attended the schools of arts and philosophy, at least during seven years, and afterwards during five years in the schools of medicine.

The books which formed the subjects of medical study were chiefly translations from the Arabic compilations from Galen and

Hippocrates (for their works were confounded together) composed by Arabic physicians, (such as the ten books of practical, and ten books of theoretical medicine of Isaac Israelita), which had been introduced into the University of Salerno towards the end of the 11th century, chiefly by Constantine the African. Theophilus was a Greek physician in the reign of the Emperor Heraclius, by whom likewise the treatise ascribed to Philaretus was written; and the work of Nicholaus was a production of the school of Salerno towards the close of the 12th century, which long enjoyed a distinguished reputation.—*Dr. Peacock's Observations on the Statutes of the University of Cambridge.*

ANATOMICAL MODELS.

THE Society of Arts, at their meeting on Wednesday evening last, voted their Gold Isis Medal to Mr. Simpson, surgeon to the Westminster General Dispensary, for the application of papier mâché to the making of anatomical figures, and models of morbid anatomy. Mr. Simpson, some years ago, turned his attention to the constructing of anatomical models, in consequence of the difficulty and expense at that time attendant on procuring subjects for dissection. The materials in general use for anatomical models were wax or plaster, of which the former was found to be too expensive to come within the means of lecturers, and students in general; and was too delicate to be handled in the lecture-room without incurring the chance of considerable damage. The plaster of Paris models were also objectionable, on account of their great weight and brittleness. The material which he uses is paper worked into moulds taken from dissections: this produces a model of extreme lightness, and so hard that it may be freely handled without danger of damage. The external surface is painted in oil-colour, representing the appearance of the dissection.

The right side of the figure which Mr. Simpson exhibited to the Society represents the superficial arteries, veins, nerves, and muscles; the left side shows the second and third layers of muscles, the deep-seated vessels, and more particularly those parts concerned in surgical operations.

The internal parts are removable, so as to exhibit the natural arrangement of the thoracic and abdominal viscera, the brain and its membranes, the spinal marrow, tongue, &c.

Mr. Simpson having conceived that his invention would be particularly serviceable for the study of anatomy in warm climates, where wax models cannot be used, nor the natural subject be conveniently dissected, he submitted some specimens to the Honourable East India Company, who some time since

purchased forty of his figures, which were sent to various settlements in India, for the use of the European surgeons, as also for the instruction of the native surgeons, who were assistants in the Company's Military Hospitals; the religion of the latter prohibiting their studying from dissections.

Wind, S.W. except the afternoon of the 6th, and morning of the 11th, when it was S. by E.

On the 5th, morning overcast, raining very heavily during the morning; afternoon and evening clear. The 6th, morning cloudy, with rain, otherwise clear. The 7th, evening overcast, with rain, otherwise clear. The 8th, alternately clear and cloudy, frequent showers of rain during the day. The 9th, generally clear; rain fell about one P.M. The 10th, generally cloudy, sun shining frequently during the day; a little rain fell in the morning. The 11th, evening cloudy, with rain, otherwise clear.

Rain fallen, 1 inch and 1/55 of an inch.

Holones and Parkelia.—These phenomena at this season of the year are frequently to be seen. On the afternoons of the 6th and 7th, shortly before sunset, both were very distinctly observable.

BY DR. WATSON.

LECTURE XXXV.

Epilepsy. Its symptoms and varieties; duration and recurrence of the paroxysms; periods of life at which they commence; warnings. Effects of the paroxysms, immediate and ultimate. Pathology. Anatomical characters. Causes.

THE great functions of the brain are sensation, thought, and voluntary motion. The influence of the will is a cerebral influence: it reaches and acts upon the muscles through the interposition of the spinal cord. Motions that are involuntary belong more exclusively to the system of the true spinal marrow. Yet cerebral changes, morbid states of the brain, may excite them.

I have shewn you that all these functions are liable, under disease, to be separately affected, and each in various ways and degrees. The number of combinations capable of arising out of disordered conditions of two, or three, or all of these functions, is very great. Yet the symptoms proper to the nervous system do arrange themselves into groups sufficiently definite and constant to allow of our giving them distinctive names, and making them separate objects of enquiry.

At the same time, as might indeed be expected, these several groups have strong resemblances to each other. They are obviously of the same family: "*facies non omnibus una, Nec diversa tamen; qualis debet esse sororum*:" occasionally the features

are so nearly alike, that we find it somewhat puzzling to determine with which of the sisters we are conversing; but usually there is some mark or other by which the individual may be identified.

Of these essentially nervous diseases, there are several in which the most prominent and obvious of the phenomena relate to the muscular system: irregular, and violent, and involuntary contractions occurring in muscles which, in the healthy state of the body, are subject to the control of the will. I have spoken of two very frightful disorders belonging to this head:—of *tetanus*, namely, in which the muscles of voluntary motion present the most striking changes, being affected with tonic spasm; while the sensibility undergoes no other alteration than what is a consequence of that spasm, pain I mean in the muscles themselves; and the intellectual functions continue undisturbed:—and of *hydrophobia*, in which the natural sensibility suffers much, and the mental functions some derangement; yet still the characteristic features of the malady depend upon the irregular and uncontrollable action of voluntary muscles.

The disease which I am next to consider is scarcely less terrible to witness, when it occurs in its severer forms, than tetanus or hydrophobia; but it is not attended with the same urgent and immediate peril to life. Yet it is, upon the whole, productive of even more distress and misery; and is liable to terminate in worse than death. You will understand that I am alluding to *Epilepsy*: a disease not painful probably in itself; seldom immediately fatal; often recovered from altogether: yet apt, in many cases, to end in fatuity or insanity: and carrying perpetual anxiety and dismay into those families which it has once visited.

The leading symptoms of epilepsy are, a temporary suspension of consciousness, with clonic spasm; recurring at intervals.

It is impossible to frame a perfect defini-

tion of epilepsy: nay, so various are its forms, so numerous its modifications, that no general description even of it can be given. It will be necessary for me therefore here (as it has been before) to describe first the most ordinary type of the disease, as a standard; and then to note the several variations from that standard which are known to occur in practice.

A man, then, in the apparent enjoyment of perfect health, shall suddenly utter a loud cry, and fall instantly to the ground, senseless and convulsed. He struggles violently. His breathing is embarrassed or suspended; his face turgid and livid; he foams at the mouth; a choking sound is heard in his wind-pipe; he appears to be at the point of death by apnoea: but presently, and by degrees, these alarming phenomena diminish, and at length cease; the patient is left exhausted, heavy, stupid, comatose: but his life is no longer threatened. And in a short time he is once more to all appearance perfectly well. The same train of morbid phenomena recur, however, again and again, at different, and mostly at irregular intervals.—This is a brief description of the most ordinary form of epilepsy.

The suddenness of the attack is remarkable: in an instant, when it is least expected by himself or by those around him, in the middle of a sentence, or of a gesture, the change takes place; and the miserable sufferer is stretched foaming, struggling, and insensible upon the earth. This fearful suddenness is expressed in the name of the disease, *ἐπιληψία*, a seizure, an abrupt invasion. The ancients, among whom the complaint was well known, superstitiously ascribed it to the malice of demons, or the anger of their offended deities. If a person was seized with epilepsy in the forum, it was considered an ill-omen, and the meeting was at once dissolved, and all public business suspended for that day: hence the disease was called *morbus comitalis*. *Morbus qui sputatur* was another of its names, because those present were accustomed to spit upon the epileptic man, or into their own bosoms; either to express their abomination, or to avert the evil omen from themselves. In this country its common designation is the *falling sickness*: or, more vaguely, *fits*. The cry which is frequently, though by no means always, uttered, is generally a piercing and terrifying scream. Women have often been thrown into hysterics upon hearing it; it is even said to have caused pregnant females to miscarry: even the lower animals seem to be sometimes startled and alarmed by a note so harsh and unnatural. Dr. Cheyne informs us that, upon one occasion, “a parrot, himself no mean performer in discords, dropt from his perch seemingly frightened to death by the appalling sound.”

The muscular convulsions are strong, irregular, and often universal. In many of the fits of which I have happened to see the commencement, the first effect of the spasm has been a twisting of the neck, the chin being raised, and brought round by a succession of jerks, towards one shoulder: and one side of the body is usually, I think, more strongly agitated than the other. The features are always greatly distorted. The brows are knit; the eyes sometimes quiver and roll about, sometimes are fixed and staring, sometimes are turned up beneath the lids, so that the cornea cannot be seen, and the white sclerotica alone is visible; the mouth is twisted awry; the tongue, thrust between the teeth, and caught by the violent closure of the jaws, is bitten, often severely; and the foam which issues from the mouth is reddened by blood. The hands are firmly clenched, and the thumbs bent inwards upon the palms: the arms are thrown about, striking the chest of the patient with great force, or bruising themselves against surrounding objects, or inflicting hard knocks upon the friends and neighbours who have hastened to the patient's assistance. It frequently happens that the urine and excrement are expelled during the violence of the spasm: and seminal emission sometimes takes place. The spasmodic contraction of the muscles is occasionally so powerful as to dislocate the bones to which they are attached: the joints of the jaw, and of the shoulder, have been thus put out; and the teeth are sometimes fractured.

When the convulsive paroxysm is over, the patient falls into a deep sleep. You might imagine that he slept from exhaustion, like a man worn out by great fatigue: but there is something more than this; the patient passes into a state of imperfect coma, or rather the insensibility continues after the convulsions have ceased. When he wakes he is often confused and incoherent for a time; by degrees, however, he resumes his ordinary appearance and condition: but he remembers nothing of what passed during the fit.

You may suppose that so much irregular contraction of the muscles of voluntary motion is not likely to occur without some derangement or modification of the functions of the circulation. The breathing is irregular, gasping, or arrested. The heart palpitates violently against the ribs during the paroxysm; the pulse becomes frequent and feeble; and sometimes it ceases to be tangible at the wrist during the height of the fit, and begins to be felt again as the spasms subside. The turgescence of the face indicates obstruction of the venous circulation; the cheeks and lips become purplish and livid, and the veins of the neck and forehead are visibly distended.

This then is one form, the most severe

and the most common as well as the best marked form, in which an epileptic attack occurs.

But there is a large class of cases, in which the symptoms are much more mild. There is very slight and transient, or even no convulsion at all; no turgescence of the face; no foaming at the mouth; no cry: but a sudden suspension of consciousness, a short period of insensibility, a fixed gaze, a totter perhaps, a look of confusion; but the patient does not fall. This is momentary; consciousness presently returns; the patient resumes the action in which he had been previously engaged, and is not always aware that it has been interrupted. Sometimes, with this temporary abeyance of the mental functions, there is some slight evidence of convulsion or involuntary action; the fingers of one hand, or less commonly of both, are moved irregularly, and without any object; or the eyes roll or are turned upwards; or the muscles of the face are twitched. Sometimes the patient is himself aware of what has been his condition, but shews some cunning in endeavouring to conceal it.

This slighter attack is called by the French *petit mal*; while the severer form is named *grand mal*. The former is spoken of also as *epileptic vertigo*, and distinguished by that appellation from the *epileptic fit*.

Of affections so different in degree, and in some respects so dissimilar in kind, you may be disposed to ask whether they really constitute the same disease. That they are essentially of the same stamp, we have this evidence; that both forms of attack occur in the same individuals. Sometimes a patient will suffer many recurrences of the epileptic vertigo, and at length will become affected with violent epileptic fits. Or the two forms will intermingle, sometimes the milder happening, sometimes the severer. In such cases we cannot doubt that the attacks are the same in nature, though different in form and degree. And when (as sometimes happens) we meet with the slighter disease alone, we cannot refuse to assign to it the character and the name of *epilepsy*.

Between the two extremes, there are many links of gradation. Sometimes the sufferer sinks or slides down quietly, and without noise, is pale, is not convulsed at all, but insensible; much like one in a state of syncope. After recovering he remains sick, languid, and confused, during the remainder of the day.

You will perceive from what I have now said, the difficulty of giving any single description of epilepsy, which will include all its varieties. It is of course still more difficult to offer a strict definition of the disease. Cullen defines it to be "muscu-

lorum convulsio, cum sopore." Dr. Copland furnishes a larger and more comprehensive definition. "Sudden loss of sensation and consciousness, with spasmodic contraction of the voluntary muscles quickly passing into violent convulsive distortions, attended and followed by sopor, recurring in paroxysms often more or less regular."

But almost every one of these circumstances may, in its turn, be wanting. There may be no convulsion; there may even be very slight and transient interruption of consciousness; there may be no subsequent coma or sopor; there may be no recurrence of the attack.

Yet I trust that you now have obtained some general notion of what is meant by an epileptic seizure. And I go on to enquire into several most important points connected with the paroxysms.

In the first place, they vary considerably in *duration*. Sometimes, as I have already stated, the seizure is slight, and does not occupy more than a moment or two of time. But even the severer attacks are often over in a few minutes. They seldom continue longer than half an hour; and probably the average duration may safely be laid at between five and ten minutes. Attacks that are spread over three, or four, or more hours, generally consist of a succession of paroxysms, with indistinct intervals of comatose exhaustion. In the long-continued fits, or in the protracted succession of fits, the patient often dies.

The periods at which the paroxysms *return* are also extremely variable. Occasionally the patient dies in the first paroxysm; occasionally, though he recovers from it, he never has another. Both of these occurrences are rare. Rather more frequently the fits occur at very long intervals; at the distance I mean of many years. Most commonly of all they revisit the sufferer at irregular periods of a few months or weeks: sometimes they are repeated at intervals of a few days: sometimes every day, or every night: and not very unfrequently they take place many times in the 24 hours. This extreme frequency of repetition belongs principally to the slighter imperfect seizure; the *petit mal*. Sometimes the fits observe a strictly *regular* period of return; but, for the most part, they are quite uncertain and *irregular*.

The *time of life* at which the fits *commence*, and the circumstances attending their commencement, are deserving of notice. They not uncommonly begin in infancy. Those fits of convulsion to which young children are subject during the first dentition, and which sometimes appear to depend upon the irritation of teething, and sometimes upon manifest disorder of sto-

mach and bowels—these fits are not distinguishable in their phenomena from genuine epilepsy; and we must reckon them as instances of epilepsy. It has been remarked by some one, that if you can trace the early history of an adult epileptic, you will almost always find that he or she suffered infantile convulsions. To what extent this is true I do not know, but I recommend it to you, as a point worth attending to in your future opportunities of observation.

The epileptic attack may come on, for the first time, at *any* age. According to Dr. Bright (whose account of the disease, though short, is particularly perspicuous), the most common periods are about the age of seven or eight years, probably about the time of the second dentition; and from fourteen to sixteen, shortly before the age of puberty. And the disease (he says) is very apt to occur for a few years subsequently to this. But sometimes the first fit has taken place between the ages of thirty and forty; in not a few cases, after sixty; and occasionally quite in the decline of life.

Dr. Bright offers a little piece of theory in respect to the periods at which epilepsy is apt to begin. It is a reasonable piece of theory, and serves to tie the alleged facts to one's memory, even if it be not yet proved to be true. Doubtless in many cases the circumstances that determine the first attack are quite accidental. But setting aside these casualties, he says, "there are leading periods in the evolution of the frame, and peculiar circumstances connected with certain periods, which may well be considered as influential in the production of the disease. In infancy, the nervous system is delicate, and easily acted upon by various causes of irritation. Then follows the trying period of teething. In a few years, the second dentition occurs. In a few years later, all the great changes connected with the age of puberty. To this follow the excesses and exposures of manhood: and, after the lapse of years, the vigour of the system fails, and many causes act to derange the nice balance of the constitution; the bowels often become sluggish; changes more or less serious take place in the structure of the arterial and venous system; and many causes, organic or functional, which had before been unable to exert an influence on the vigorous frame, acquire power from its relative weakness."

The first accession of the disease takes place more commonly before than after puberty. Of 65 epileptic women, in whom the onset of that disease and the first period of menstruation were carefully noted, 38 had epileptic fits before, and 28 not till after that period.

The attacks are very apt to come on during the night; in the commencement of

the disease they frequently are *confined* to the night: they are said chiefly to occur at the moment when the patient is *sinking* into sleep, or awaking from sleep. How far this is true I cannot tell. When the disease is *yielding*, the fits often happen in the night only; so that after they have, for a certain period, taken place in the daytime, or during the day and night indiscriminately, it is reckoned a good prognostic sign if they begin to restrict themselves to the night. Some patients, under these circumstances, suppose that the physician has particular remedies that will make the fits happen in the night rather than in the day; and they ask for these remedies.

Sometimes each paroxysm arrives unannounced and unexpected; sometimes distinct *warnings* of its approach are given. The latter is less frequent than the former. Georget affirms that premonitory symptoms do not occur more than four or five times in 100 cases. I am sure that this is much understated. When warning symptoms do happen, they are sometimes spread over a considerable period; several hours, or a whole day: sometimes they just last long enough to enable the patient to remove from a situation in which a fall would be attended with unusual danger; to dismount from horseback, to lie down in a boat, to get away from the fire-place, from the edge of a precipice, from the vicinity of water, to assume the horizontal position of his own free will and in his own manner, or to give notice to those about him of what is going to befall him. In some cases the warning is too short and sudden even for this. The *kind of notice* that he receives is very variable indeed. Often it consists in some unnatural state of the mind, the feelings, the temper; the patient is fidgety, irritable, low-spirited, timid, sullen; or, on the other hand, he feels unusually strong, and hearty, and cheerful. Sometimes there is a notable change in some one or more of the natural functions, or of the bodily sensations; the patient loses his appetite, or his appetite becomes voracious; a great flow of urine takes place; he smells an ill smell, is aware of a strange taste, hears extraordinary noises, or sees spectral illusions; not mere specks floating before him—*muscæ volitantes*—but distinct forms of persons and things. This is not very common, but it certainly happens. The late Dr. Gregory, of Edinburgh, was assured by a patient of undoubted veracity, that always when he had a fit of epilepsy approaching, he fancied that he could see a little old woman in a red cloak, who came up to him, and struck him a blow on the head, and then he immediately lost all recollection, and fell down.

Headache, and giddiness, and dimness of vision, are all of them common symptoms

among those which have been observed to be precursory of epilepsy. Sometimes there are circumstances which are obvious to the bystander: a flushing of the face, or lividity; difficult articulation; vomiting. Of 21 epileptics treated in the hospital, at Wilna, by Joseph Frank, vomiting announced the paroxysm in 7. Some of the uneasy feelings are apt to come on and continue even for several days previously to the attack; restlessness in particular, disturbed sleep, distressful dreams, a peculiar and sudden coldness of the extremities. An internal *working* is a phrase often used by such persons to express a sensation which is probably indescribable.

But the most curious precursory symptom of all, if we except the spectral illusions, is what is called the epileptic *aura*. This is a sensation which is likened, by different patients, to different things; to a stream of warm or cold air, to the trickling of water, to the creeping of a spider. The sensation proceeds commonly from some distant part of the body, from one of the extremities, from a thumb, or finger, or toe, or from some spot on the trunk, and runs along the skin, towards the head; occasionally it gets no farther than the epigastrium: as soon as it reaches the head, or stops at the epigastrium, or elsewhere, the patient's consciousness forsakes him, and the paroxysm declares itself.

There seems to be some analogy between this epileptic aura and the well-known sensation, to be spoken of hereafter, of a ball rising from the stomach to the throat, and constituting the *globus hystericus*; except that in cases of epilepsy the sensation commonly begins in an extremity, and not in the stomach; and the fit comes on when it reaches the head, and not the throat. Sometimes, I think, these two sensations are blended.

In some instances, spasms of the muscles of the part whence the aura proceeds are observed to take place prior to the more general state of spasm.

This aura is certainly a very curious phenomenon. It has been thought to depend upon some change propagated along the nerve upwards to the brain, and that it is sometimes connected with some injury done to, or some morbid impression made upon, an afferent nerve. I think that this explanation may apply to some cases.

In a patient of my own, who was subject to epilepsy, the warning sensation commenced in one of his thumbs, which presently after began to be twisted inwards; but by tying his handkerchief tightly round the thumb, he could prevent the fit. Dr. Seymour mentions the case of an epileptic boy, who had learned to protect himself

against a threatened paroxysm, by biting his tongue.

In other cases the aura probably originates in some change within the head, and is analogous to the numbness or tingling that is often felt in some part of the body or extremities immediately before an attack of palsy or apoplexy. There is no real inconsistency in this twofold explanation: the source of the aura may be centric or eccentric; as I shall explain to you, in due time, the exciting cause of the paroxysm may be.

A knowledge of these warning circumstances is clearly of importance, always as far as respects the comparative security of the patient during the attack: sometimes as affording us the opportunity of staying off the fit altogether. And it is necessary to remark, that they sometimes give, as it were, a *false alarm*; they occur, and yet, although no measures of prevention are taken, no paroxysm follows.

The phenomena that *succeed* the paroxysm are also of great interest and moment.

I have already apprised you that the convulsions terminate in general before the insensibility is over: the patient draws, perhaps, two or three deep sighs, and ceases to struggle. Some few persons are quite themselves again in a few moments; some appear to recover consciousness, and then fall into a deep and prolonged slumber; but many do not regain their consciousness at all upon the cessation of the convulsions, but remain in a state of profound stupor, from which however they can generally be roused for a time. This state of coma (for it is nothing else) has been known to last a week: after the patient emerges from it, he is sometimes merely languid and inert; sometimes he is like a person stunned, or in a state approaching to idiocy, which gradually clears up; sometimes he is furiously delirious for a short time; not unfrequently there is a degree of partial paralysis, which also usually soon goes off, though it occasionally is permanent; the eyes are fixed, or he squints, or the pupils are dilated, or he drags a leg, or he falters in speech. Most commonly he speaks of headache, or discomfort of some kind.

It is very seldom that the patients have any recollection whatever of what has passed during the fit. Many of them are not aware that they have had a fit; and those who do know it, discover the fact by finding themselves wet or dirty; by the injuries they have received during the convulsions; by the soreness of the bitten tongue; by the bruises of their limbs; or by the confused or painful sensations which they subsequently experience, and which they have learned to associate with the conviction that a fit has

happened, by having been informed on previous occasions, when they felt the same sensations, that they had suffered a paroxysm of insensibility and convulsions.

Upon the whole, it is seldom that any ill effect can be noticed as having been left behind it by any one single fit; but, alas! this cannot often be said of their repetition.

Doubtless a single paroxysm does often leave the patient in a worse condition than that in which it found him; but this does not become perceptible to an ordinary observer, until after the alteration has been rendered apparent by repeated fits, and repeated small additions to the permanent injury. The friends of the patient perceive that his memory is enfeebled in proportion to the number of the attacks; that his mental power and intelligence decline. His features even assume, by degrees, a peculiar character; and too often he sinks into hopeless fatuity, or confirmed imbecility or insanity. It is this tendency which renders epilepsy so sad and fearful a disease.

Foville affirms, that the intellectual degeneration is more constant, and comes on more early, in persons who are principally afflicted with the epileptic vertigo, the *petit mal*, the imperfect seizure, than in persons in whom the *grand mal*, the violent and decided paroxysm, takes place. Dr. Copland, on the other hand, is of opinion, that "the more severe the fits, the more is that result to be dreaded." This is a point which can only be settled by statistical facts. And as we all have the opportunity of collecting some such facts, and of adding them to the general stock, I mention this, and some other points that are still uncertain or disputed, as worth bearing in mind. More, probably, depends upon the *repetition* of the fits, than upon their *precise nature or severity*. Cases do occur in which epileptic persons preserve their faculties to a good old age; but those who are early epileptic do not often attain old age; and *whenever* the disease comes on, if it repeats itself frequently, it is much more often than not followed by impairment of the mind, or by some apoplectic or paralytic affection, which implies and accompanies the mental change. You will sometimes hear the cases of Julius Cæsar, of Mahomet, or of Bonaparte quoted, as examples of high intellectual power, existing and remaining in spite of epilepsy:—and it is allowable, perhaps, to make use of such cases for comforting the friends of epileptic persons; or for giving the advantage of sustained hope to the patient himself. But, in truth, these cases are not worth much. Napoleon is said, I know not upon what authority however, to have suffered something like epilepsy during sexual intercourse; this is not very uncommon in persons subject to that disease. And, with

respect to Julius Cæsar, we learn from Suetonius, that it was only in the latter part of his life that he laboured under epilepsy; and that he had two attacks while engaged in business.

Having now described the phenomena of epilepsy; the periods of life at which it is most apt to commence; its varieties; and its tendency and termination: let us next enquire what is known respecting the real seat and nature of this strange and melancholy complaint.

The functions that are affected are clearly the functions of the *brain*: sensation, thought, and motion regulated by the will, are the natural functions of that organ. The temporary abeyance of sensibility, thought, and volition; and violent and irregular action of the muscles, which are thus withdrawn from the empire of the will; constitute a paroxysm of epilepsy. We have, in this malady, another illustration of the fact, that when the controlling influence of the sensorium is suspended, the peculiar functions of the spinal marrow are exercised, not only in a disorderly, but also in an unusually energetic manner. That the brain and the spinal marrow, though physiologically distinct, are yet intimately connected with, and dependent upon, each other, a thousand familiar facts assure us; and there are good reasons for believing that the change, whatever it is, which is the immediate precursor and cause of the epileptic fit, may sometimes originate in the spinal cord, and thence extend to the brain; and sometimes originate in the brain, and communicate itself to the spinal cord. Dr. Marshall Hall's doctrine, that all convulsive diseases are diseases of the spinal marrow, cannot be properly applied to this convulsive disease of epilepsy. It is true that the spinal cord is concerned whenever there is convulsion; but it is concerned in every *voluntary* movement also, through the instrumentality of the brain itself; and it may be, and often is, irregularly influenced by a disordered and unnatural state of the brain. Tetanus may fairly be regarded as a disease of the cord, and its proper appendages; the spasms arise and reach their height, while the powers of thought and sensation are undisturbed, and while the volition remains, although the morbid condition of the cord renders it ineffectual. In epilepsy, these cerebral functions are always implicated. There is *always* a loss of consciousness: and in the epileptic vertigo, the *petit mal*, there is frequently a suspension of consciousness only, *without any convulsion at all*. The brain, therefore, we must consider to be essentially concerned in this disorder.

What the precise state of the nervous matter may be, which determines the loss of

consciousness and the spasms, we can only conjecture. A derangement in the relation between the arterial and venous circulation within the head; a temporary pressure somehow arising; a determination of blood towards the head; a diminution of the natural quantity of blood sent thither from the heart; all these have been assigned as possible causes of the paroxysms. Plausible reasons might be given in favour of the operation of each of them; but the speculation is more curious than useful. We have not yet penetrated the mystery of these remarkable phenomena, and it will be more profitable to turn to another question, which admits of a somewhat more definite answer, viz. :—what is the *morbid anatomy* of epilepsy?

Suppose that a person who has had epileptic fits, but in whom they have not been followed by any durable affection of the intellectual or locomotive functions, dies of some other malady; and you have the opportunity of minutely examining the condition of the nervous system. Often you will find nothing at all which can throw any light upon the occurrence of the epileptic paroxysms; no appreciable alteration whatever in any part either of the brain or of the spinal cord. In other cases you may discover some organic disease within the head: a scrofulous tubercle, a spiculum of bone projecting from the skull. Have we then detected the cause of the disease? All that can be said is, that the piece of bone or the tubercle was probably a *predisposing* cause of that derangement of the nervous substance which determined the paroxysms; the derangement itself, if, indeed, it was of such a nature as to be cognizable by our senses, has gone, with the symptoms; the tubercle or bone having in the meantime remained without any sign which could betray its presence.

M. Foville, whose testimony in this matter is entitled to much weight, affirms that in persons who have been subject to epilepsy, uncomplicated as yet with any permanent disorder of the intellect, or of the faculty of voluntary motion, and who have died *in the fit*, constant alterations are observable within the head; viz. a strong injection of the vessels of the encephalon: the membranes, the brain, and the cerebellum, are gorged, he asserts, with livid blood. But he goes on to say that this is to be ascribed to the mode of death; that we see the same appearances in persons who have died by hanging, or any form of apnoea; that they are not peculiar to epilepsy, and do not explain the attack, but only point out the way in which it has been fatal.

If such appearances were uniformly found in the heads of persons who die suffocated, or who die in a fit of epilepsy, this observation

of M. Foville's might be a very just one. But I doubt whether such internal congestion of the vessels of the head is met with in either case: for reasons formerly explained to you. In the only two instances in which I have had the opportunity of examining the state of the brain after death by hanging, there certainly was no such congestion.

It is, I fancy, a very common notion, both that such congestion does take place, and that it is the cause of the paroxysm: and it may be worth while shortly to state the reasons which are opposed to the conclusion, that the congestion (granting for the moment that it does happen) is a sufficient explanation of the attack.

In the first place it is not easy to conceive that the congestion could so suddenly arise and subside again, as it must sometimes do, if it be the immediate determining cause of the fit: within the space of a single minute, for example.

And in the second place, the signs of external congestion and plethora, by which signs we measure the amount, if there be any, of the *internal*, are most marked just when the symptoms of the paroxysm begin to subside and disappear. So that we cannot, I think, look upon the congestion as the *cause* of the convulsive symptoms.

Let us go a step farther, and enquire into the state of the encephalon in those persons who, having suffered epilepsy, had, before death arrived, been affected with some permanent impairment of the mental functions, or (what often goes along with such impairment) with some degree or other of muscular paralysis or debility.

The most common alterations met with in the brain in such cases are the following.

Induration of the white matter of the brain, which presents a dull appearance; sometimes, besides the hardening, a general injection of the white matter; and in the majority of cases a marked dilatation of the blood-vessels. In some instances the consistence of the white matter is diminished, it is soft and flabby; but there is the same dilatation of the blood-vessels. These changes pervade the whole of the white matter in every part of the brain. At the same time the grey matter is found irregular on its surface, mottled or of a rosy colour in its substance, and sometimes altered in consistence. And in many cases the membranes are found to be adherent in some parts to the convolutions with which they lie in contact.

Such are the results of the experience of careful observers in respect to the morbid anatomy of epilepsy; of Morgagni, of Foville, and of MM. Bouchet and Casauvielh. The changes last described are such as are produced by chronic inflammation of the brain and its membranes. They are the *consequences* (I imagine) of re-

peated paroxysms of epilepsy; they are the very same as are frequently met with in cases of insanity complicated with paralysis, and they elucidate, therefore, the connexion of these affections: but they certainly teach us little or nothing of that actual condition of the nervous mass upon which the epileptic paroxysms depend. And, in truth, to expect to find in the brain the traces of convulsions that have passed away, would be as unreasonable as to expect to find the traces of former voluntary movements.

Of those organic changes which may be regarded as strong predisposing causes of the paroxysms, my own experience accords with that of Dr. Bright; who states, that they are more frequently such as affect the surface, than the deeper-seated parts of the brain: tumors external to the cerebral matter, alterations in the bones of the skull; or in the membranes that envelope the organ. Various altered states of the spinal marrow have also been recorded.

But besides the morbid appearances that are *sometimes only* visible in the nervous centres themselves, there are others, which it is of great importance to attend to, situated in other parts of the body, and at a distance from those centres: diseased states of the liver; biliary concretions; renal calculi; stones in the bladder; worms in the alimentary canal; diseases of the uterus; and of various other parts. And these morbid conditions have often, no doubt, an intimate connexion with the epileptic paroxysms. Accordingly some authors make almost as many varieties of epilepsy as there are organs of the body; they specify the cerebral, the spinal, the cardiac, hepatic, gastric, intestinal, nephritic, genital, uterine, and so on. It will be sufficient, however, to consider two species only; that, namely, in which the disease originates in the nervous centres themselves, and especially in the brain; and that in which it originates in some other part. Most persons who have written on epilepsy make this distinction, although they employ different terms to express it. Cerebral and occasional; primary and secondary; idiopathic and sympathetic; centric and eccentric. The two last terms are the best. But let us clearly understand them. The disease may, in one sense, be considered eccentric, even when it is situated in the brain; eccentric, *i. e.* in respect to the true spinal marrow. But I apply the epithet centric to epilepsy when its cause lies in either of the two great nervous centres; the brain, or the cranio-spinal axis. The distinction itself we shall find to be an important one, both as regards the prognosis and the treatment. But I must first say a few words respecting the causes, and the diagnosis of epilepsy.

There is no doubt that a tendency to epileptic disease is frequently *hereditary*. It may be derived from parent to child; or it may skip over a generation or two, and appear in the grandchild or great grandchild; or it may be traceable only in the collateral branches of the ancestors. This is just what takes place in other hereditary maladies. You may often notice also that other forms of nervous disorder prevail in the same families.

MM. Bouchet and Casauvielh found that among 110 instances of epilepsy, 31 were hereditary. Of 321 persons afflicted with epileptic insanity, and seen by Esquirol, 105 were descended from insane or epileptic parents.

Again, a tendency to epilepsy is very often found to go along with an *unnatural form of the head*, which is pinched up like a sugar-loaf; or misshapen and unsymmetrical, one-half being unlike the other; or oddly configured in some way or other. Epilepsy is no uncommon attendant of chronic hydrocephalus.

And thirdly, the *scrofulous diathesis* is a strong predisposing cause of epilepsy. Dr. Cheyne even holds that epilepsy is as certain a manifestation of the strumous disposition, as tubercular consumption, or psoas abscess. Now of the two predisposing circumstances last mentioned, it may be observed, that they commonly merge in that which preceded them: the strumous diathesis, and a particular conformation of the head, are both very likely to descend from parents to their progeny.

Whether the sex has any influence in determining a predisposition to epilepsy, is a question that remains to be settled. Foville thinks it is most common in females; Dr. Elliotson in males. I have certainly seen more epileptic boys and men, than girls and women. But the casual experience of a single observer is not enough to determine the point. We want numerical statements on a large scale. At the close of the year 1813 there were 162 male epileptics in the Bicêtre; 289 female cases in the Salpêtrière. Jos. Frank observed that, of 75 patients, 40 were females.

REPORT UPON THE MORTALITY OF LUNATICS.

BY WILLIAM FARR, Esq., F.S.S.*

THIS report, which has been drawn up at the request of the Council of the Society, is founded on the reports of the Hanwell Asylum, returns from the Bethlem Hospital, and the valuable series of tables submitted to the Society last

* Read before the Statistical Society of London, 15th March, 1841.

year by Colonel Sykes. It was thought desirable that the mortality of lunatics in two of the largest public institutions of the country should be compared with the mortality in the licensed proprietary houses; and that, if the mortality differed, the differences should be investigated, and traced to their causes by the methods of statistical analysis which we now possess.

The condition of lunatics in this country has, within the present century, attracted much public attention; and in 1807, 1815, 1816, and 1827, the management of the asylums provided for their confinement was investigated by Committees of the House of Commons. Many abuses were brought to light; and the last committee, of which Mr. Gordon was chairman, stated in their report, after a searching and able inquiry, that the abuses discovered in 1815 still existed. They "repeated, adopted, and confirmed" the recommendations of the committees of 1807 and 1815. Enactments subsequently passed the legislature; and several county asylums (among which that of Middlesex deserves to be particularly mentioned), have since been erected. No parliamentary inquiry has been instituted since 1827; but Mr. Ewart has given notice of his intention to move in the House of Commons for the appointment of a committee in the present session of Parliament.

The persons of unsound mind in England amount to several thousands. They are usually of middle age, frequently parents, and are of all conditions and ranks of life: 494 lunatics confined under the Crown possess property yielding an annual income of £317,154*. Men of the highest intellectual rank—men of genius—are not exempted from the visitations of this disease: it stoops to the lowest, and disorders the meanest brain. It makes the labourer a pauper, and too often ruins the families of the middle classes. 6402 idiots, and 7265 lunatics, have been returned to Parliament as paupers. Such a disease, which disorders the senses, perverts the reason, and breaks up the passions in wild confusion;—which assails man in his essential nature,—brings down so much misery on the head of its victims, and is productive of so much social evil—deserves investigation on its own merits by statistical, as well as other methods. But it has an additional claim upon the attention of the Society.—A considerable portion of the insane are under confinement, and have to be provided for or watched over by the State, which, as it permits them to be deprived of liberty, is bound to afford them protection, and to assure them the best means of restoration to health.

Great improvements have taken place in the treatment of lunatics. In the best asylums they are no longer shut up in cells like wild beasts, nor punished by harsh keepers. Their chains have gradually been struck off. A further step has been attempted. At the Middlesex asylum no strait-waistcoats, straps, or other instruments of personal coercion, have been used since the 21st of September, 1839. The experiment was first tried at Lincoln, and it is now contended by persons of experience, ability, and integrity—by Mr. Hill, Dr. Conolly, and the visiting justices of Middlesex,—that in a house properly built, with skilful medical supervision, and a sufficient number of humane and intelligent keepers, personal coercion should be abolished. This is denied by other gentlemen of equal humanity, who maintain that, although all restraint *may* be dispensed with, the strait-waistcoats should still be employed as a remedy in the paroxysms of mania. A keen controversy has been waged on the subject. Asylums not only differ widely in the extent to which restraint is carried, but in the space allotted to patients in their employment, food, and medical treatment. The cost of criminal lunatics at Bethlem is 15s. a-week; of idiots or lunatics in the workhouses, 2s. 10d. to 3s. 6d. a-week. Some of the asylums are under the control of the visiting justices, others are visited by the Metropolitan Commissioners. The hospitals of Bethlem and St. Luke are not visited at all, but are managed by the officers and governors; while a very large number of lunatics are farmed out, or confined in workhouses, by the parish authorities.

Amidst these various circumstances and conflicting systems, we ask which is the most advantageous? And it will be replied by all parties,—“that is the best system under which the greatest number of lunatics recover their reason in the shortest time.” But in a slow disease, presenting so much diversity in individuals, it is evident that the superiority of any system of treatment can only be determined by the average results, by a comparison of the recoveries and deaths; in fine, by statistics. [Here follow a variety of calculations thrown into the tabular form, the general result of which is to demonstrate that the annual mortality of both male and female paupers in the licensed houses was nearly twice as great as the mortality of paupers at Hanwell, and twice as great as the mortality of other lunatics in the licensed houses.]

What is the mortality among lunatics in favourable circumstances? Is insanity a fatal disease?—Upon the latter question there has been a considerable diversity of opinion. Some lunatics live to an advanced age. Of 213 admitted by Dr. Conolly at Hanwell, 15 were aged 60 and upwards, and

* See Parliamentary Return, Session 1839, No. 378.

1 was between 70 and 80; and 58 in 753 at Hanwell had been labouring under the disorder between 20 and 50 years. In 1835 an action (Fisher v. Beaumont) was brought at the York Assizes to recover from the *Providence Assurance Company*, £2000, insured upon the life of the Rev. Mr. F***. In charging the jury, the judge said that they had to consider whether insanity had a tendency to shorten life? If insanity had such a tendency, they must find for the defendant; if not, for the plaintiff. The medical evidence was conflicting; and the jury, after a short deliberation, found for the plaintiff, on the ground that insanity had no tendency to shorten life!*

We have no means of ascertaining the mortality of lunatics at large; but the mortality of lunatics in asylums is much higher than the mortality of the general population, and the excess cannot be ascribed entirely, although it may partially, to the confinement, the unwholesomeness, or the usages of mad-houses. The mean age of lunatics in asylums is about 35-40. The average age of the patients admitted at Bethlem, (1830-34) was 36 years (36.2); and the mean age of 213 admitted at Hanwell by Dr. Conolly was 36½. The mortality at the age 30-40 is 1.2, and at 40-50 is 1.5 per cent. in England and Wales. In cities the mortality at a corresponding age is not more than 2 per cent. annually. Now the annual mortality at Bethlem, where dangerous cases are carefully excluded, was 9 per cent. in 1827-39. At Gloucester, one of the county asylums, at which the treatment is the most successful, the diet is generous and nutritious, and the patients live as much as possible in the open air,—the annual mortality is 7 per cent.

The annual mortality of severe cases of insanity cannot, I think, in favourable circumstances, be less than 6 per cent.; so that the mortality is three times greater among lunatics, than among the general population, at the same age. We have seen, however, that the annual mortality among the better class of patients in the licensed houses was 11 per cent., among paupers at Hanwell 12 per cent., among paupers in the licensed houses 21 per cent., and among pauper men at one licensed house 27 per cent.;—as high as the rate of mortality experienced by the British troops upon the western coast of Africa, and by the population of London when the plague rendered its habitations desolate!

To what is this excessive mortality to be ascribed—to the disease, or to the treatment?—The question cannot be positively answered, nor can the causes of the difference in the mortality be determined, without a

careful examination of all the circumstances. I shall briefly notice the chief causes to which the mortality of lunatics in asylums *has been, or may be, ascribed.*

The visiting justices of Hanwell state as "an extraordinary and disgraceful fact," that numbers of patients are sent into the asylum, as it would seem, to die. Of 636 deaths, 64 occurred within a month after admission. A similar complaint is made at many hospitals; and there is probably a tendency to send dangerous cases, or cases in their most critical stage, to public institutions. The exclusion of such cases from Bethlem reduces the mortality, but they cannot all be excluded without giving the asylums the advantages of that *selection*, which is so profitable to assurance offices. For in a disease so fatal as insanity, a certain number of lunatics are necessarily on the verge of death at the period of the disease when admission into an asylum is usually sought; and a due proportion of such cases cannot fairly be excluded.

Reference has also been made to the fact that out of 834 patients in Hanwell on December 31st, 1839, about 655 had been in other asylums, or workhouses, for considerable periods. Many cases were admitted in the chronic stages of insanity; but this, though it will account for a smaller number of recoveries, and the high proportion of fatal cases, will not account for a high *annual rate* of mortality. The *annual rate* of mortality is greater in the acute than in the chronic state of insanity. Thus, at the hospitals of Bethlem and St. Luke the annual mortality among the class called "curables" was 11 per cent., and only 6 per cent. among "incurables" (chronic cases). At Hanwell the annual mortality of lunatics in the state of mania, monomania, or melancholia, appears, so far as it can be determined, to be about 12 per cent., while in cases of incoherence, imbecility, or dementia (chronic stages of insanity), about 8 per cent. die annually.

A return in the Hanwell Report shews the numbers admitted during each separate year into the asylum, and the numbers discharged cured, relieved, or dead, year by year. The return extends from May 16th, 1831, to September 30, 1840. From this table we learn that 422 lunatics were admitted in the year 1832; that 55 of them were cured or relieved, and 55 died during that year, leaving 312 to enter upon the next year (1833), when 27 of them were cured or relieved, and 31 died; and so on, year succeeding year, until September 30th, 1840, when 137 remained in the asylum. The patients admitted in 1831, and in 1839-40 (the two last years), have been set aside; and the 1389 lunatics admitted in the seven years (1832-38) have been followed to the

* MED. GAZETTE, August 8th, 1835.

end of 1839. The 422 lunatics, it may be assumed, were admitted at equal intervals of time in 1832, or the middle of the year 1832 may be taken as the mean time of their admission; whence it follows, that of 422 admitted in the year 1832, 55 died in the *half-year* following, 31 in the next *year*, &c. The table, therefore, permits us to

trace 422 lunatics admitted in 1832, to death, recovery, or relief, during $7\frac{1}{2}$ years; and 325 admitted in 1838 to the end of 1839, or for a period of only $1\frac{1}{2}$ year. The subjoined table presents a summary of these interesting facts, which in the form of publication are analogous to the tables of lives published by the *Equitable Society*.

Table of the Deaths and Recoveries in different stages of Insanity.

| Years. | Entering on each period. | In the succeeding periods. | | | Remained in the Asylum at the end of the Period. |
|--------|--------------------------|----------------------------|-----------|-------|--------------------------------------------------|
| | | Cured. | Relieved. | Died. | |
| 0· | 1,389 | 125 | 25 | 152 | 0 |
| 0·5 | 1,087 | 142 | 13 | 130 | 208 |
| 1·5 | 594 | 14 | 9 | 42 | 30 |
| 2·5 | 499 | 9 | 0 | 45 | 46 |
| 3·5 | 399 | 10 | 2 | 28 | 51 |
| 4·5 | 308 | 6 | 2 | 20 | 34 |
| 5·5 | 246 | 4 | 0 | 21 | 66 |
| 6·5 | 155 | 4 | 1 | 6 | 144 |

The table is read thus :—Of 1389 lunatics entering upon the *first* period ($\frac{1}{2}$ year), 125 were discharged cured, 25 relieved, and 152 dead in the next *half-year*; of 1087 who entered upon the *second* period, 142 were discharged cured, 13 relieved, and 130 dead in the subsequent *year*, at the end of which 208 were lost sight of. For the reason before stated, it will be observed

that the *first* period extends to the end of the 6th month; the second from the end of the 6th to the end of the 18th month; the third from $1\frac{1}{2}$ to $2\frac{1}{2}$ years, &c.

From this arrangement of the facts, the annual rate of mortality and recovery in the several stages of insanity, subsequent to admission, at Hanwell, may be deduced.

Table of the Number of Insane Persons living, cured, and dead; and of the Annual Rate of Mortality in different stages of Insanity.

| No. | Period of the disease from the date of Admission. | Number living one year. | Cured or relieved. | Died. | Out of 100 living, one year. | |
|-----|---------------------------------------------------|-------------------------|--------------------|-------|------------------------------|-------|
| | | | | | Cured or relieved. | Died. |
| | Years. | | | | | |
| 1 | 0 $\frac{1}{2}$ | 619 | 150 | 152 | 24·2 | 24·6 |
| 2 | 0 $\frac{1}{2}$ 1 $\frac{1}{2}$ | 944 | 155 | 130 | 16·4 | 13·8 |
| 3 | 1 $\frac{1}{2}$ 3 $\frac{1}{2}$ | 1033 | 32 | 87 | 3·1 | 8·4 |
| 4 | 3 $\frac{1}{2}$ 5 $\frac{1}{2}$ | 673 | 20 | 48 | 3·0 | 7·1 |
| 5 | 5 $\frac{1}{2}$ 7 $\frac{1}{2}$ | 383 | 9 | 27 | 2·3 | 7·0 |
| | 0 7 $\frac{1}{2}$ | 3652 | 366 | 444 | 10·0 | 12·2 |

The numbers stated to have been *relieved* were 14 per cent. of the numbers *cured and relieved*; and as the proportion remained nearly the same through the seven years, the two classes of facts have not been distinguished.

The annual rate of recovery in the *first half-year* was 24 per cent.; and the rate of mortality was nearly 25 per cent. The two rates remain high in the *second period* (the rate of recovery 16, and of mortality 14, per cent.), while they declined respectively

to 3, and to 8 per cent. in the *third* period; and to 2·3, and 7·0 per cent. annually, between the $5\frac{1}{2}$ and $7\frac{1}{2}$ years after admission into the asylum.

The rate of mortality in an unit of time increases as the malady advances up to a certain point, and then declines regularly, in all diseases which have hitherto been investigated arithmetically. In cholera the rate of mortality is highest at 18 to 24 hours; in small-pox, the mortality is highest from the 10th to the 15th day; in consumption the

rate of mortality appears to be greatest from the 6th to the 9th month. The variation in the rate of mortality and recovery in small-pox is shewn below :—

| Days of the Disease* | 5—10 | 10—15 | 15—20 | 20—25 | 25—30 | 30—35 | 35—40 |
|----------------------------|------|-------|-------|-------|-------|-------|-------|
| Daily Deaths in 100 living | 6·4 | 31·5 | 27·2 | 8·5 | 4·3 | 2·8 | 2·0 |
| Daily Recoveries in 1000 | ·1 | ·2 | 1·8 | 9·2 | 19·7 | 34·8 | 47·5 |

Insanity is regulated by analogous laws ; and a majority of the patients are admitted at Hanwell before the disease has passed the point at which the mortality declines, although many are admitted afterwards, when the rate of recovery is reduced much more than the rate of mortality.

At Hanwell, 18 in 100 living die annually in the first $1\frac{1}{2}$ year ; and 8 in 100 annually for 6 years afterwards. If an asylum, therefore, contained none but persons in the first year and a half of the disease, (after admission is always understood,) the mortality would be 18 per cent. ; while it would be 8 per cent. in an asylum for chronic cases between $1\frac{1}{2}$ and $7\frac{1}{2}$ years. Without implying any disparagement to the treatment in the former case, the rate of recovery

in the two asylums would differ in a still greater degree, as it would be 19 per cent. in the first asylum, and only 3 per cent. in the second, set apart for the exclusive reception of the advanced cases. This separation seldom takes place in practice. The chronic and acute cases are always mixed in an institution like Hanwell ; but it is evident that in the first years after it was opened, the proportion of cases in the early stages must have been greatest, and the proportion of lunatics in advanced periods of the disease must have since progressively increased. According to the above laws, the proportion of deaths and recoveries should gradually have declined ; and this was the fact.

| Periods of Three Years. | Lunatics† existing One Year. | Died. | Recovered. | Annually out of 100 living. | |
|-------------------------|------------------------------|-------|------------|-----------------------------|------------|
| | | | | Died. | Recovered. |
| 1831-3 | 1147 | 197 | 165 | 17·2 | 14·4 |
| 1834-6 | 1754 | 194 | 119 | 11·1 | 6·8 |
| 1837-9 | 2121 | 215 | 168 | 10·1 | 7·9 |

The annual mortality was 17 per cent. in the first three years, and 10 per cent. in the last three years ; the annual rate of recovery was 14 per cent. in the first, and 8 per cent. in the last period. In the licensed houses which have been many years in existence, the annual rate of mortality was 13·6 per cent. in 1833-36, and 17·2 in 1836-1839 !

When the rates of mortality and recovery in the several stages of insanity are ascertained, the effects of treatment and external influences can be compared in asylums containing the various classes of patients, in proportions as different as at Hanwell in 1831-33, and 1839-40. The rule is :—multiply the number of lunatics existing at the several periods of the disease by the corresponding rates of mortality and recovery (0·242, 0·246, &c. &c.), and the sum of the products will represent the number of deaths and recoveries. By this rule the deaths in Hanwell during the $1\frac{1}{2}$ year, ending September 10th, 1840, should

have been about 149, and they were 128 ; the numbers cured or relieved should have been about 126, and they were 154.

It will be found by this rule that the rate of mortality among paupers in the licensed houses and in Hanwell, has differed less than the first result of the returns would lead us to suppose, although it has been excessive in both. The paupers remain little more than a year and a half (1·67) in the licensed houses, in which the annual mortality was 21 per cent. ; at Hanwell the annual mortality in the first $1\frac{1}{2}$ year after admission was 18 per cent.

From the facts given at page 25, part of a table of mortality and recovery may be constructed for lunatics.—(See top of next page.)

If we take 1,000 lunatics at the stage of the disease corresponding to the time of admission at Hanwell, 217 will be discharged (108 recovered or relieved, and 109 dead) in the half-year following, leaving 783 to enter upon the second period, to be reduced year by year, until at the end of seven years and a half only 310 remain. The range of the present series of observations extends no further, but the relative proportion of recoveries and deaths remains nearly as 88 to

* British Medical Almanack, 1838, p. 212.

† Deduced from annual enumerations of the males and females ; the years of life=5,022. From daily enumerations the years of life=46,39.

| No. | Period of the Disease dating from the day of Admission | The Number of Lunatics who | | | Cases terminating in each Period. | | |
|-----|--------------------------------------------------------|----------------------------|---------------|------------------|-----------------------------------|--------------|-----------|
| | | Enter upon each Period. | Will Recover. | Will Die Insane. | Total Number. | By Recovery. | By Death. |

| 6 | 4.5 | 418 | 116 | 302 | 41 | 11 | 30 |
| 7 | 5.5 | 377 | 105 | 272 | 35 | 9 | 26 |
| 8 | 6.5 | 342 | 96 | 246 | 32 | 8 | 24 |
| 9 | 7.5 | 310 | 88 | 222 | .. | .. | .. |

222 during the last six years: and to complete the scheme of the table it may be assumed that 88 of the 310 will recover, and 222 will die. The columns *b*, *c*, shew, therefore, that of 1,000 cases, 380 will recover, and 620 die; that at the end of a year and a half, 160 will recover, and 410 will die.

The columns *e*, *f*, shewing, first, the numbers cured ("or relieved," is understood invariably); and, secondly, the numbers dying in each period are readily deduced from the table before given. Thus 150 were cured, and 152 died in the first half-year, out of 1,389 cases; consequently, 108 were cured, and 109 died out of 1,000 cases, which form the basis of the new table. As 217 cases terminated during the first half-year, 783 entered upon the second period, when the amount of recovery having been = $\frac{150}{1087}$, and the mortality = $\frac{152}{1087}$, exactly 112 recovered,

and 101 died. By continuing the process, the deaths and recoveries are obtained for each year. The columns *a*, *b*, *c*, are obtained by the successive subtraction of the numbers in columns *d*, *e*, *f*, and the first number (620) in column *c*, is the sum of those who died in the $7\frac{1}{2}$ years. = 398×222 , the number who, it is presumed, will die insane *after* that period.

The numbers representing those who will die and recover (columns *b*, *c*.) decrease at a uniform rate after the second year, and the seven terms of the series, column *c*, are obtained by multiplying the last (222) successively by 1.1075 (log. 0.044338); the six terms in the series, column *b*, are deduced in the same way, from 88 raised successively by the rate 1.0966 (log. 0.040072). The two series of numbers obtained by the hypothesis agree very closely with those directly deduced from the observations—

| Years . . . | | 1½ | 2½ | 3½ | 4½ | 5½ | 6½ | 7½ |
|-----------------------|--------------------|-----|-----|-----|-----|-----|-----|-----|
| Numbers to die insane | Direct observation | 417 | 376 | 330 | 298 | 271 | 239 | 226 |
| | By Hypothesis | 410 | 370 | 334 | 302 | 272 | 246 | 222 |
| Numbers to recover | Direct observation | ... | 138 | 129 | 115 | 104 | 98 | 87 |
| | By Hypothesis | ... | 139 | 127 | 116 | 105 | 96 | 88 |

Halley invented the Table of Mortality, which consists of three columns, shewing the number of persons who die or survive in each successive year. The events it exhibits are of one kind; all the persons die. But cases of *disease* may terminate in two ways—by death, and by recovery. A different tabular construction was therefore required for sick persons, such as the one preceding, from which the *mean future duration*, the *probable duration*, the *probability of recovery*, and the *probability of a fatal termination* in any given time, can be determined at any period of the disease.

The *mean future duration of insanity*, or the *expectation of disease*, cannot be deduced from the preceding table, because it breaks off at the end of $7\frac{1}{2}$ years: but if the annual rate continued the same (1.10), 7 of 310 would remain insane 40 years, and the mean future duration of insanity at the period of admission at Hanwell would be 6.7 years; at the end of half a year it would be 8 years: and after $1\frac{1}{2}$ year, it would be 10 years.

In the six years 1834-39, when the inmates were = 3,875 living 1 year, 706 were discharged: one in 5.5 therefore was dis-

charged annually. If the institution had existed several years, and the numbers admitted and discharged had been equal, the mean duration would have agreed with this, and have been 5.5 years; but as Hanwell was opened in 1831, and only 1,179 out of 2,029 admitted, had been discharged on the 30th September, 1840, the 6.7 years is probably nearer the true mean duration.

In determining the mean term of treatment, which was attempted in the early part of this paper, it may at first sight seem that the years of residence should have been divided by the mean of the numbers admitted (2,029), and discharged (1,171). This method would make 4.8 years the mean term of treatment in the six years ending 1839—(for $\frac{2,029}{800} = 4.8$); and 1.9 year the mean term of treatment in 1831-3; when 920 were admitted, 362 discharged, and the years of residence were = 1,248. Divide 1,248 by the number discharged (362), and 3.44 years would be the given term of treatment; but even this, as the experience of the six following years evinces, is much below the truth. The errors are the same as if the division of the children under three years old by the mean number of births and deaths, or by the deaths alone, were supposed to give the expectation of life at birth; whereas the division by the deaths at that early period, though the nearest approximation of the two, gives a less number than the expectation of life in years.

Dr. Conolly ascertained the previous duration of the disorder in 191 cases (exclusive of 10 congenital cases) admitted during the year; 66 had been labouring under the disease less than six months; 26 between 6 and 12 months; 24 between 1 and 2 years; and 1 had been insane 39 years. The mean previous duration was 3.4 years. But, as little more than *half* the number had been insane *twelve months*, the time of admission may be represented by 1, or by $1\frac{1}{2}$ year.

The mean age of 213 persons at admission was $36\frac{1}{2}$ years; the mean age of 195 at the time of the *first attack* of insanity was stated to be $32\frac{1}{2}$ years.

The *probable future duration of insanity* has been shewn to be $2\frac{1}{2}$ years at the time of admission; for, in $2\frac{1}{2}$ years, the 1,000 cases are reduced to 509. The chances that a patient will, or will not, remain insane $2\frac{1}{2}$ years, are 509 to 491, or nearly equal. Among those who remain insane half a year after admission, the probable future duration of the disease is nearly 4 years.

The *probability of recovery* at admission = $\frac{2,029}{1,000} = .380$; of dying insane = $\frac{620}{1,000} = .620$. Half a year after admission the probability of recovery is $\frac{2,722}{838} = .347$; of dying insane $\frac{513}{838} = .653$. The numbers in juxtaposition, in columns *b* and *c*, express the

respective chances of death and recovery; thus, $5\frac{1}{2}$ years after admission at Hanwell, the chances are 272 to 105 that a lunatic will *not recover*. All these probabilities depend more or less on the assumption that 88 in 310, remaining at the end of $7\frac{1}{2}$ years, will ultimately recover.

The *probability of recovery, or of dying*, within any year, or years, up to $7\frac{1}{2}$, is accurately shown by the table. In the first half-year the *probability of recovering* is $\frac{1,028}{1,000} = .108$; the probability of recovering in $3\frac{1}{2}$ years is $\frac{386-1,27}{1,000} = .253$. Out of 1000 cases, 253 recover in that time; hence .253 is the probability of recovery. The *probability of dying* in the first half-year is = $\frac{1,028}{1,000} = .109$; in the two years following $\frac{513-270}{738} = \frac{1,243}{738} = .180$.

From a table of this kind the lives of lunatics can be insured; and, from the present table, they may be insured for a limited number of years.

The table is an instrument by which the effects of treatment on the mortality, the number of recoveries, and the duration of all diseases, can be accurately measured. It enables us to compare two or three different plans of treatment, and to determine their effects upon the principal results at which all medical treatment aims—the reduction of the mortality, and of the duration of the disease. Thus if 139, of 509 lunatics that have been $2\frac{1}{2}$ years in Hanwell, will recover under the present treatment, and 200 recover under any new mode of treatment that may be introduced, the advantages of the latter would be obvious; and still more so, if the *probable duration* of the disease were reduced from 10 to 5, or 2, years.

The returns from the licensed houses do not state the ages; and the ages of a few lunatics are given in the interesting Report of Dr. Conolly. From other observations it is known, generally, that the mortality increases, and that the probability of recovery declines, as age advances.

The sex, age, and stage of the disease, are the principal internal causes that influence the mortality, except the form of the disease which, exclusive of congenital idiotcy, may be, perhaps, reduced to an element already discussed—the “stage of the disease.” The influence of complications, of sex, and of age, may be assumed to be nearly the same in the licensed houses and Hanwell, as in ordinary asylums—the asylum, for instance, at Gloucester, where the mortality does not exceed 7 per cent. annually. The mortality of 7 per cent. may be fairly ascribed to insanity. The excess above this must be attributed to the diseases generated by the limited space in which the unhappy lunatics are confined; to the collection of large numbers under the same roof; the impurity

of the atmosphere; the want of exercise and warmth; the poor unvaried diet; and the deficiency of medical attendance*. But the influence of these agents can only be ascertained by a parliamentary inquiry; and it will not be denied that the causes should be investigated which raised the mortality of lunatics above the standard—57 per cent. among private patients, 71 per cent. at Hanwell, and 200 per cent. among paupers in the large licensed houses!

The Bethlem Hospital differs essentially from the Hanwell Asylum, as well as from the majority of the licensed houses, in the stricter selection of patients for admission. By the rules, the following cases are inadmissible:—lunatics who have been insane for more than twelve months; who have been discharged uncured from other hospitals; in a state of idiotcy; afflicted with palsy, or with epileptic or convulsive fits; and suffering from any dangerous disease. Notwithstanding the instructions in the admission papers, the petitions of 58 out of 311 (19 per cent.) who applied in 1836, were rejected. The patients are not allowed to remain

longer than one year. 253 lunatics admitted in 1836 had been insane 83 days, on an average; 117 had been insane less than a month.

It would be exceedingly interesting to determine the mortality of this selected class of lunatics for 12 months. But, if dangerous symptoms come on at Bethlem, the patients are dismissed, when practicable, as *improper objects*. Thus of 3026 discharged in 10 years, 829 were dismissed uncured, 483 as *improper objects*, and 145 died. A great number of the “improper objects” would die soon after they left Bethlem; and their dangerous state, or supposed incurability, was the alleged cause of their dismissal. Paralysis, however slight, even of a finger, is the forerunner of death in the insane; and of 210 dismissed as improper objects (1831-36), 87 were paralytic, 59 “sick and weak,” 24 epileptic, 4 apoplectic, 2 had “fits,” and 28 were idiotic.

The lunatics at *Bethlem* are divided into three classes: “curables,” “incurables,” and “criminals.”

Curable Lunatics, 1827-39.

| | Men. | Women. | Total. |
|-------------------------------------------------------------|------|--------|--------|
| Admitted | 1168 | 1797 | 2875 |
| Discharged | 1145 | 1654 | 2799 |
| Discharged as cured | 545 | 961 | 1506 |
| Improper objects | 236 | 166 | 402 |
| Dead | 75 | 69 | 144 |
| At request of friends | 19 | 17 | 36 |
| Uncured | 254 | 422 | 676 |
| Leave of absence expired | 16 | 19 | 35 |
| Out on leave of absence | 49 | 73 | 122 |
| Years of life | 637 | 1002 | 1639 |
| „ (exclusive of those out on leave of absence) | .. | .. | 1371 |

21 of the lunatics on the list of the hospital were constantly out on leave of absence; and during the 13 years, 122 individuals were discharged as “out on leave of absence.”

Of 100 “curable” patients discharged, 54·5 were cured, 5·2 died. The mean term of treatment was 586 year, = 7 months; or 49 year, = 6 months, if the time spent out of the hospital, on leave of absence, be excluded. The lunatics discharged as “im-

proper objects” were 14·5 per cent.; a considerable portion of whom would have been numbered with the dead if they had remained.

The annual mortality was 8·8; the recoveries 92 per cent.; 24·5 per cent were discharged as improper objects; 43·4 were discharged uncured; 2·1 were out on leave of absence. 171 were discharged annually out of a constant population of 100.

If the deaths which occur among those out on leave of absence are not recorded, the annual mortality to 100 resident in Bethlem is 10·5.

Incurables.—72 “incurables” were admitted; 72 discharged (33 men, 39 women), and the average number resident for 13 years

* The diet and the condition of lunatics at Hanwell have been latterly ameliorated very considerably by the Visiting Justices, at the suggestion of the present accomplished Physician; and the mortality may be expected to be reduced in proportion. It is also right to state that in some licensed houses the mortality of private patients does not exceed 7 per cent.

was 64·2. The years of life were therefore = $64\cdot2 \times 13 = 834$. Nine incurables were cured, 39 died, and 24 were discharged at the request of their friends.

Of 100 cases 13 recovered, 33 did not recover, and 54 died. One in 11·6, = 6 per cent. were discharged annually; the mean term of residence was 11·6 years. 1 in 21, = 4·7 per cent. died, and 1 per cent. was cured annually.

"Incurables" is an improper term; but it is a recognition of the law that recovery is infrequent in advanced stages of insanity.

Criminals.—In the 13 years 71 criminal lunatics were admitted at Bethlem (56 men, 15 women); 51 were discharged, namely, 26 died, 2 escaped, and 23 recovered. The average number resident was 57·3, the years of life 745.

Of 100 cases, 45 recovered, 51 died. The annual rate of mortality was 3·5, of recovery 3·1 per cent.; the mean term of treatment deduced from the years of life, and the number discharged, was $14\frac{1}{2}$ years. The numbers admitted and discharged in the 11 years (1827-37) were nearly equal (36 and 39); and the years of life divided by the number discharged = $\frac{633}{39} = 16\cdot7$ years.

It is evident that several of the criminals, such as Oxford, cannot properly be said to labour under insanity—in the sense of a disease. It is, if any thing, like idiocy, a congenital misdevelopment of the brain.

The number of recoveries is considerable at Bethlem, but less than at some private asylums, notwithstanding the careful selection of cases. The mortality is reduced by excluding dangerous cases, and by dismissing the patients on the verge of death as "improper objects." It is difficult, under these circumstances, to account for the death of nine or ten in 100 annually, upon any other supposition than that the mortality is high at the early stage of the disease in Bethlem.

The last Committee of the House of Commons on Lunatics, stated in their report, "It has been clearly established in evidence, that there is no due precaution *with respect to the certificates of admission, to the consideration of discharge, or to the application of any curative process, to the mental malady**." Lunatics under confinement, it should be well recollected, are *prisoners*; and every one will admit that the depriving a man of his personal liberty, or turning loose a lunatic on society, are acts involving great responsibility,—a responsibility which, if it exist at all, is very imperfect in the present state of the law. In order to deprive a lunatic of his estates, a formal inquiry is publicly instituted; but a person who has been seven days chargeable to the parish may be committed as a lunatic

to the County Asylum by two justices of the peace on the certificate of *any* physician, surgeon, or apothecary, asserting that the "said person *appears* to be insane of mind." 2,780 pauper lunatics are confined under these certificates in the county asylums*. But there are 1,389 lunatics, and 7,007 idiots, "under the care of the parish officers as in-door or out-door paupers." Many of them are necessarily under restraint, without either warrant or certificate; which is only required when the parishes think it necessary to send them to a public asylum, where their treatment costs two or three times as much as the workhouse fare.

Paupers may be sent to licensed mad-houses by a justice, or by the officiating clergyman and overseer, with one medical certificate; and other persons may be sent to a licensed house by any layman, upon the certificates of *any two* medical men†. It appears also that by law, any person whom the governors choose to admit as a lunatic, may be confined at Bethlem, or St. Luke's Hospital, for an unlimited time.

The liberation of persons in confinement as lunatics, takes place under no better regulation. Medical visitors have been appointed, in the words of Lord Lyndhurst, "to see that the Chancery lunatics are well cared for, but above all *to watch the least glimmering of returning sanity, and see that the parties are not detained one day longer than necessary.*" The relatives, parish officers, proprietors, justices in petty-sessions, and the Metropolitan Commissioners, release lunatics from the licensed houses; but the mode in which this is effected is by no means satisfactory. "When once," says Colonel Sykes, "they (pauper lunatics) get shut up in a mad-house, it is indeed difficult for them to regain their liberty‡." Lunatics are discharged at the discretion of the visiting justices from the county asylums; by the governors from Bethlem, St. Luke's, and other hospitals supported by subscription; and by the parish officer from workhouses.

Many cases of abuse have occurred under the present system, which will be probably thought by the Society to require extensive alterations. And although there would be much difference of opinion on many points, all will probably agree that *no person should be placed under restraint as a lunatic in asylums, hospitals, or houses of any kind, who has not been examined by a public officer, practically acquainted with insanity.* I would therefore suggest that by some modification of the present system of inspec-

* Return to the House of Commons, 5th July, 1836.

‡ Journal of the Statistical Society, vol. iii. p. 116.

* Report, 1827, p. 4.

tion, the circumstances of every lunatic confined should be investigated personally by a crown officer, and recorded previous to commitment, at the expiration of every quarter of a year after admission, and at the time of dismissal. The sex and age, the stage, form, and complications, of insanity, should be registered, on entering and leaving the several institutions, by impartial officers. This would be a protection to lunatics, and to the public; the deaths and recoveries would be registered on a uniform plan, and an invaluable statistical check on the results of treatment would be obtained.

We may then discover the causes of insanity, the laws which regulate its course, the circumstances by which it is influenced, and either avert its visitations, or mitigate their severity; perhaps, in a later age, save mankind from its inflictions, or, if this cannot be, at any rate ensure the sufferers merciful treatment.

SOME
PHYSIOLOGICAL REFLECTIONS
ON
THE NATURE AND TREATMENT OF
ANGINA PECTORIS,
AND OF ANALOGOUS STATES.

BY T. WILKINSON KING,
Lecturer on Pathology at Guy's Hospital.

[For the Medical Gazette]

[Continued from p. 183.]

Dr. Heberden's account of angina. Theory of the first attack; the idea of spasm; of the state of the left ventricle; of the right ventricle; of the aorta.—Cases: remarks.

OUR former introductory remarks concerning the heart in its exalted states of activity, and in its deteriorations as life advances, will be seen to apply to all forms of cardiac disorder, though in very various degrees. We may now approach more closely to some specific considerations.

It is, perhaps, impossible to find a simple history of angina, unless we should take some single recorded instance: but this remark is introduced, to explain, in a measure, the obscurity and confusion in which the subject has been involved by the additions made to the characters, without any distinction of cases, by many successive authors.

The following description of angina pectoris, which was first especially noticed and named by Heberden, is

extracted from his Commentaries on the History and Cure of Diseases, as presenting a plain account of the affection, and a proper introduction to some remarks as to its nature and pathology.

“There is a disorder of the breast marked with strong and peculiar symptoms, considerable for the kind of danger belonging to it, and not extremely rare, which deserves to be mentioned more at length. The seat of it, and sense of strangling and anxiety with which it is attended, may make it not improperly be called angina pectoris. They who are afflicted with it are seized while they are walking (more especially if it be up hill, and soon after eating) with a painful and most disagreeable sensation in the breast, which seems as if it would extinguish life, if it were to increase, or continue; but the moment they stand still, all this uneasiness vanishes. In all other respects the patients are, at the beginning of this disorder, perfectly well, and in particular have no shortness of breath, from which it is totally different. The pain is sometimes situated in the upper part, sometimes in the middle, sometimes at the bottom of the os sterni, and often more inclined to the left than to the right side. It likewise very frequently extends from the breast to the middle of the left arm. The pulse is, at least sometimes, not disturbed by this pain, as I have had opportunities of observing by feeling the pulse during the paroxysm. Males are most liable to this disease, especially such as have passed their fifteenth year. After it has continued a year or more, it will not cease so instantaneously upon standing still: and it will come on not only when the persons are walking, but when they are lying down, especially if they lie on the left side, and oblige them to rise up out of their beds. In some inveterate cases it has been brought on by the motion of a horse or a carriage, and even by swallowing, coughing, going to stool, or speaking, or any disturbance of mind. Such are the most usual appearances of this disease; but some varieties may be met with. Some have been seized while they were standing still, or sitting; also upon first waking out of sleep: and the pain sometimes reaches to the right arm, as well as to the left, and even down to the hands; but this

is uncommon: in a very few instances the arm has at the same time been numbed and swelled. In one or two persons the pain has lasted some hours, or even days; but this has happened when the complaint has been of long standing, and thoroughly rooted in the constitution. Once only the very first attack continued the whole night. I have seen nearly a hundred people under this disorder, of which number there have been three women, and one boy twelve years old; all the rest were men near or past the fiftieth year of their age. Persons who have persevered in walking till the pain has returned four or five times, have then sometimes vomited. The termination of the angina pectoris is remarkable; for if no accident intervene, but the disease go on to its height, the patients all suddenly fall down, and perish almost immediately; of which, indeed, their frequent faintnesses and sensations, as if all the powers of life were failing, afford no obscure intimation. The angina pectoris, as far as I have been able to investigate, belongs to the class of spasmodic, not of inflammatory complaints; for—

In the first place, the access and the recess of the fit is sudden.

2dly, There are long intervals of perfect health.

3dly, Wine and spirituous liquors, and opium, afford considerable relief.

4thly, It is increased by disturbance of the mind.

5thly, It continues many years without any other injury to the health.

6thly, In the beginning it is not brought on by riding on horseback, or in a carriage, as is usual in diseases arising from scirrhus or inflammation.

7thly, During the fit the pulse is not quickened.

Lastly, Its attacks are often after the first sleep, which is a circumstance common to many spasmodic disorders."—Chap. 70, *Pectoris dolor*, page 303.

Now, with respect to the term angina, we have no doubt but that it has been much too indiscriminately used. The sudden anomalous diseases of the heart cannot be all of one kind; indeed the early and simple attack, and the later and complicated paroxysm, are widely different, and it is equally certain that one specific state, with a serious train of symptoms in a strong heart, may give place to another in a

wasted organ, and thus become the cause of death. If we desire to know what to seek, and where to look, for the explanation of different cases, we must regard the relative importance of every part, the condition of each, and its burthen in comparison of its powers of resistance or contraction.

It is almost unimportant, perhaps, to enforce the fact, that Heberden's notice refers to widely opposite states: here the pulse unaltered, there actual fainting; in one case the sufferer may exert himself to produce several attacks in succession; in another, he is seized in bed, or upon the occurrence of very moderate mental excitement. The pains, the feelings of distress, and the characters of the patients, are equally various: boys and women, adults and old men, will hardly allow us to reason in the same train for all cases.

In the primitive attacks of angina in a person said to be healthy, we find little or nothing more than the full exercise of the circulatory and respiratory functions impeded for a moment—embarrassed, as it may seem, by the failure of some particular part. We place the fault in the left ventricle and its orifices. The lungs experience a transitory turgescence, which is at once relieved by standing still; as the venous valves and right heart are thus left at ease, and the left ventricle and aorta, which are also directly relieved by the comparative suspension of muscular exertion, are allowed to regain a capacity which admits of more easy play, and complete action.

Why the subsequent attacks are successively more slow in subsiding, is to be explained probably by reference to the very same opinion, that we should advance to account for the more ready production of the attacks in the later periods of the disease. It seems natural enough that the defective parts, whatever they may be, should become more and more deranged permanently, and also more susceptible of actual disturbance, as by incompetence when overtasked, and thus, in fine, less and less able to regain or return to their proper functions with facility.

Some may be inclined to inquire, can it be, as spasm is produced in young and muscular persons by exertion (as in the gastrocnemii), that so the ventricle may become contracted spasmodically?

We are very unwilling to suspect this, for the affection does not seem ever to be accompanied by spasm of any voluntary muscles, nor, indeed, is the age of angina that of muscular spasm or true cramp, and still less can we suppose that the subsequent attacks occur in an organ susceptible of such contractions. If the disorder were of this kind, it would hardly manifest itself as it does: not to be at once fatal, to be relieved by resting, and to be capable pretty constantly of other and better explanations (as we think), are excuses enough for a brief notice of spasm at this time. But, assuming the general fact of the exalted state of the heart's functions, previous to the first anginal seizure, the free diastole and systole of ventricles, and fullest play of the valves, let us inquire which is the part to be most suspected of failure. The first reply would be, surely, that part which is originally the weakest, or which may be already the most defective, or which possesses the least power of regulating its own efforts; and all this, as we suppose, points to the aortic valves. The force which might over-distend the left heart depends on the right ventricle, and is in a measure regulated by the lungs; the power which dilates the aorta and its orifice is the over-excited left ventricle.

As to the right heart, we cannot here enter upon its peculiarities; and as to the mitral valve, we are not unwilling to admit that it may suddenly become imperfect, and especially supposing the aorta has first yielded to excess. If the affection were located in the right heart, we should rather expect it as the sequel of sudden exertions and obstructed breathing, than of the state of second wind. But the fact of a safety valve in this part is a sufficient objection to the application of the views which may be contended for with respect to the left heart, where the valves are naturally strong and close, although they may suddenly become inadequate. Imperfect valvular action on the right side is relief; on the left side, especially if sudden, it is almost death. Supposing, however, the full play of the thoracic organs to be brought about steadily, it is evident that the less the reflux on the right side, the more the efforts of the lungs and left ventricle would be required.

When the views of a safety-valve

function in the right ventricle come to be considered with attention, there will be no need of much argument to show that the right heart, at times, has a very close and efficient propulsive action; but it may require some additional reflection to show that, with gradually increasing calls to exertion, and only moderately increased distension, the force and precision of this part of the circulation is still uninterrupted by reflux, and especially if the cavity be well nourished, as in the prime of life, or before the due proportions of this period are materially altered.

On the whole it is most manifest that, up to a certain moment, all the circulatory actions of a propulsive kind may be unrestrained and copious. We would suppose no need, or at least the smallest effect, of a safety valve. We would not allow that disturbance in the right ventricle should make itself felt in the way of angina. We put the difficulty in the left ventricle. Does this cavity become suddenly inefficient, and primarily, thus involving the mitral valve, &c.? We are not inclined to this as a common explanation, with respect to a strong or healthy ventricle.

If, however, it be possible for any state to be brought about by which particular parts may be rendered inefficient, we shall leave it to others to show what is so likely to occur as the undue yielding of the aorta*, and the consequent incompetence of its valves, under the impulses of the blood from the most powerful cavity, in its most violent efforts, the arterial system being at the same time subject to varying degrees of obstruction.

Of course we are here considering only the first onset of the active form of angina, or rather of one single form.

The observations of the most severe and certain disorganizations of the aortic valves we conceive to be sufficiently corroborative of our present opinions. These are cases of marked distress, and differ chiefly from angina in being permanent, and more speedily or certainly fatal. In angina the heart more or less suddenly receives an increased quantity of blood, and is oppressed. In the original cases of retroverted valves, recorded by Dr.

* There may be a case in which the mere dilatation of the aorta gives rise to pain.

Hodgkin in the *MEDICAL GAZETTE* (vol. iii. p. 443), or at least in the most marked of these, the characters of angina are but little concealed. The left ventricle being permanently oppressed is to be compared to the same cavity in the end of old angina, or in the state of the weakest heart.

The following case of angina will serve to illustrate the defective condition of the aortic valves. It occurred under the observation of Mr. H. H. Handey, of Upper Stamford Street, to whom we are indebted for the history.

Mr. A. F. M., *æt.* 47, a spare and leucophlegmatic person, had an injury eight years ago, which was supposed to have fractured the spine; and five years back he suffered from a fracture of the skull. He was subject to flatulence and dyspeptic symptoms, with palpitation, and a pulse which sometimes intermitted about every eighth beat. On ascending a hill in June 1839, he experienced his first anginal attack; he was obliged to stop, and ultimately return home. Some brandy and water seemed to relieve him. The second attack was three months afterwards, and the pain was more acute. About a fortnight later, after sitting up two nights and days with a patient, another paroxysm came on; he was bled to the amount of sixteen ounces, and went to bed; but at last became so ill that he was obliged to be conveyed to his own house. On the second day Mr. Handey saw him in the morning, a paroxysm having just passed off. His countenance was anxious, and the pulse feeble. A draught of warm water appeared to have given him relief. In the evening Mr. Handey was called to him in a fresh attack; the countenance was expressive of great agony; the pulse quick, but feeble; and he complained of intense pain across the chest, extending to near the insertions of the deltoid muscles, with sensations of choking, and of palpitation, and also of a feeling of coldness down the back, which he himself referred to the region of the descending aorta. He spoke of his lungs as if sewed in a vice. Some warm tea induced eructation; and he gradually grew easier. He took some rhubarb, and rhubarb with calomel, and continued easy for a week; after which, in one day and night, he experienced five several attacks, each lasting from five to five-and-twenty minutes.

Warm water, tincture of opium, and brandy and water, all seemed to relieve him temporarily.

At this period he was ordered

Pulv. Opii, gr. j.; Pil. Hydrarg. gr. iv. Omni nocte sumend.

And a draught, to be taken twice a day, consisting of *Magnesiae Carb. gr. xv.; Ol. Pimentæ, gtt. j.; Tinct. Gent. Tinct. Aurant. aa. ʒiiss.; Aquæ, ʒix.*

Good diet with bottled porter were likewise enjoined, and gradually the fits decreased in violence and duration, and were reduced to two in the twenty-four hours; and on the third day he travelled 136 miles to London, hoping that his native air might prove beneficial. One fit occurred on the journey, and for nearly a month he went on improving, with attacks diminishing in frequency and severity; but towards the expiration of this period, having spent a pleasant evening with a few friends, and retired in apparent health and spirits, he was heard to fall in his room, and was immediately after found lifeless.

The severity of this gentleman's attacks was such that all around him seemed to consider it matter of astonishment that he had lived so long.

The examination of the body was performed by Mr. Jonas King, nearly three days after death. The body was that of a tall narrow-chested man. The costal cartilages were soft. There was a considerable quantity of fat on the abdomen and chest. The lungs were pretty healthy. There was about a table-spoonful of bloody fluid in the pericardium. The heart was large, fat, and flaccid. Both ventricles were a good deal dilated: the right was of its natural thickness. The substance of the ventricles was firm and pale, and the act of cutting into the left ventricle, more particularly, elicited a sound like that produced by cutting cartilage with scissors, but in a very slight degree. All the valves were uniformly thin, except the mitral, which had two or three small patches of thickening. The aortic valves offered pretty well-marked corpuscula; and the upper parts of the valves were occupied by large perforations, angular and broad—one or two in either half of each valve. These seemed to take up nearly all the natural surfaces of contact, yet there were some partial traces of contact below them. The aorta was rather small and thin

Sketch of the Aortic Valves, shewing numerous and large perforations in those parts of the curtains which have been opposed to corresponding parts of the adjoining curtains. There may still be seen slight surfaces (or traces) of contact below the free edges, or perforations*.

throughout. In its lining, immediately above the valves, was a narrow line of opaque deposit, chiefly anteriorly. The coronary arteries seemed rather small. The stomach was healthy, and contained only a few small pieces of undigested matter. The liver was rather firm, but decomposing as well as the kidneys (which were soft), and earlier so than other parts. The spleen was large.

REMARKS.—It is to be observed, that the former injuries which this gentleman suffered had induced long rest to the whole body, and this may have been the cause of the perforations of the crescentic valves. The peculiar sense of thoracic constriction we may refer to the lungs in dependence on sudden impediment in the left heart.

We would by no means assert that all the pains described in this case were not from the physical pressure of the heart: the choking and palpitation may belong alone to the same state of distension.

With respect to the estimation of the

* Surfaces of contact indicate the quantities of surplus curtain and of ordinary valve. The surplus curtain is called into use when the great tube dilates, but if contraction of the membranes or perforations in their edges, or both, coincide with dilatation of the tube, the circulation is proportionably impeded.

influence of remedies, it is most evident that posture and rest, the state of digestion, and of the general secretions, at the time of the seizures, must be taken almost momentarily into the account, as well as the tendency to spontaneous subsidence of the paroxysm, before we can form a judgment.

As to the fatal issue, we may suppose that cheerfulness was but an evil guide, whether we regard the inducements to indulgence, or the temptation to a little unusual activity of the limbs; the state of the stomach indicated plainly that digestion had just added its last to the circulating mass.

It is not our intention to assume positively that the aortic valves were concerned in the production of death, but we do not doubt that they were the cause of the primary attack, and we suspect of all.

The perforated crescents were the only object which we had previously directed attention to, and requested should be brought away.

At page 753 of the last volume of the *MEDICAL GAZETTE*, a preparation is described (No. 1396, in Guy's museum), and to this we may again refer. The aorta is much dilated and diseased; its valves are materially perforated, as in the foregoing case; and the ventricle

is very much dilated and enfeebled. Some faintings preceded a fatal syncope. Here we may observe, that in proportion as the attack is easily produced, the painful sensations are not excited, the distension being but slight. It is not intended to advance these cases as proofs so much as illustrations of our meaning. The last approaches more to the state of feeble hearts, on which we shall not dwell at this time.

No. 1302, in the Guy's museum, is a "heart in which there is hypertrophy and dilatation of the left ventricle, and dilatation of both auricles, without adhesion of the pericardium, and little if any valvular disease. The patient, about 55 years of age, died very suddenly: he had long been affected with dyspnoea, but was not anasarcaous." Dr. Hodgkin has recorded this man's case; and I quote it for the sake of remarking, that the lacteal absorption was going on abundantly, which is an indication so far of health, while the sudden and unexplained death may well be supposed to have depended on the additions thus made to the burden of the heart or lungs.

In continuance we observe, that there is probably some degree of difference between every ulterior anginal attack and that which preceded it; but the contrast between the earlier and later attacks may serve to explain a very distinct form of the disease.

We cannot but suppose that, from the first, the disproportionate states of the heart are liable to increase; for instance, dilatation supervening on wasting of a cavity may be said to lay more than a double burden upon a part which is less than half as strong as formerly.

But now let us compare the tolerably sound heart of one case with the wasted and deteriorated organ in another. Is it not manifest that the debility of the ventricles may render them susceptible of being overwhelmed by distension from the slightest cause. Even in sleep, in the recumbent posture, when, perhaps, besides the disadvantages of the more easy access of blood to the right ventricle, digestion may still be adding to the accumulation of blood, and by slow degrees the ventricles are filled to a point beyond endurance, and the manifestation is sudden enough. When syncope is not to be feared, the erect

posture should tend to relieve this, by freeing both arteries and veins; the legs should hang over the bed, perhaps, and the muscular system be left to exert the least influence on the vessels. Of course, this is not a case to suppose distension of arteries, although they may be too full for the weak left ventricle.

We have had the pleasure of considering and discussing the topics before us with Dr. Joseph Ridge, who has very carefully and successfully investigated them. Dr. Ridge has collected some cases of sudden death in vigorous persons, from simple obstruction in the orifices of the coronary arteries; and it may be hoped that he will shortly publish his views of enfeebled and wasted hearts, as also of angina generally. For this reason, we have for the present avoided all particular reference to the absolutely failing heart, although it will be found that this is a topic on which our reflections are constantly verging.

We hope that already it may be seen that these kinds of reflections will help to explain many symptoms. And they do not derogate from the fact, that although distension is an essential condition of almost every case of which we treat, the chief inconvenience may be in different parts, and in different forms. It is evident that when the heart is most susceptible of disturbance, the patient's merely turning cautiously on his bed may so impede the aortic circulation, or drive on such an additional quantity of venous blood, as to induce a paroxysm. On the other hand, we may enforce a strong contrast in the case of an organ whose disturbance is set up with much difficulty, and with difficulty maintained or aggravated.

The gigantic farmer, mentioned by Dr. Forbes in a note, seized in good health with a simple anginal attack, set his horse into a canter, (an easy pace) let his arms hang down, and balancing himself with as little muscular exertion as possible, endeavoured, as he thought, to overcome the distressing disorder, while in truth the heart or aorta was endeavouring of itself to regain the limits of easy action, being already in a degree relieved by an easier motion of the body, and by gravitations, &c. This, at least, is our

explanation, and we can well say that this, and the preceding case, we have tried experimentally, and pretty thoroughly, with respect to dyspnœa.

[To be continued.]

ON DILATATION BY FLUID PRESSURE

IN STRICTURE OF THE URETHRA.

To the Editor of the Medical Gazette.

SIR,

I SHALL feel obliged by your inserting in the next number of the *MEDICAL GAZETTE*, the following description of instruments used in stricture of the urethra.—I am, sir,

Your most obedient servant,

JAMES ARNOTT.

21, Fitzroy Square, London,
May 8th, 1841.

Although our knowledge of the pathology of stricture of the urethra has been much extended by the labours of Hunter and others, the treatment of this very common and distressing disease differs at the present day in no very material circumstance from that which was followed two hundred years ago. In the works of Wiseman, published in the reign of Charles II., the various practices now had recourse to will be found described. He mentions the use both of metallic and soft bougies; the application of caustic is noticed, a practice which was revived by Hunter; and cases are related in which the operation of opening the urethra behind the stricture was performed, instead of puncturing the bladder—an expedient of which the late eminent Sir Astley Cooper has been deemed the original proposer.

Unfortunately, this stationary condition, during the progress of almost every other department of surgery, has not proceeded from the treatment of stricture having attained perfection. On the contrary, it is acknowledged to be an opprobrium of the art. The means employed are admitted, by conscientious and intelligent surgeons, to be, in almost every case, but palliative; and although stricture may generally be much relieved by such means applied from time to time, it cannot be denied that the irritation which accompanies organic changes in a part of so much

sensibility as the urethra, will, by long continuance, often produce other disease in the neighbouring organs of the urinary and generative systems, which is sure to embitter, if it does not shorten, the life of the sufferer.

It is now many years since I introduced to the profession an account of practices in the treatment of stricture which I had had sufficient experience to recommend as substitutes for the very imperfect and sometimes hazardous measures in common use. But because the apparatus recommended was of rather a complicated description, as compared with that usually employed, and because part of it was constructed on mechanical principles, with which surgeons generally were not familiar, it has either not been used at all in this country (where the French modifications of plans of treatment I had proposed in impervious stricture, and of a new method of applying caustic, are almost unknown), or in so imperfect and erroneous a manner, as to disappoint expectation.

The purpose of this paper is to describe a modification, which I have lately contrived, of the instrument employed in the dilatation of stricture, combining the essential requisites, for general use, of simplicity of construction and easiness of application; and I cannot doubt, from its great and manifest superiority over the means commonly had recourse to, in the degree of relief afforded by it, and the safety and quickness with which this is obtained, that it only requires to be known to be immediately adopted.

Dilatation of stricture has been effected in two ways: by instruments which operate on the principle of the wedge, opening the constricted part as they advance in the canal, of which description are bougies and sounds; and by instruments which are themselves capable of distension, and which, by being made to enlarge in diameter whilst within the stricture, exert their dilating force from the centre directly outwards, or, as it may be termed, eccentrically. Amongst the principal advantages of eccentric dilatation over that of the wedge, when effected by a proper apparatus, are—that instruments so operating, having no tendency to stretch or tear the urethra in front of the stricture, by pushing on the stricture after having passed partially

through it, the surgeon is enabled by their means to use greater force (if required) with safety, than with rigid bougies and sounds, which have this tendency; that there is no danger, from the opposition to the passage of the instrument being erroneously attributed to the stricture instead of the wrong direction of its point, of the surgeon's piercing the side of the canal, and causing effusion of urine, or false passage; that the dilatation being effected without irritation from friction, and following the yielding structure, may be rapidly made; that the whole of a long stricture is dilated at once, or several strictures are acted upon at the same time, instead of the action being nearly confined, as in the case of the bougie, to the front or face of the first stricture; and that, from the power of enlarging the instrument in the interior of the canal to any size, the dilatation of the diseased part may be carried to any greater extent than the diameter of the outer orifice of the urethra, so as to afford the best means of effecting a permanent cure.

The apparatus used for dilatation, on the principle just explained, consists essentially of a strong membranous tube of fixed dimensions, which is placed, in its empty or collapsed state, within the stricture, and then injected with fluid. I have used such a fluid dilator, with various modifications, according to peculiarities of cases. The form of instrument most easily constructed and applied, and which has not as yet been described, is merely a varnished silk tube of the required diameter, and of a length to extend from the orifice to a little beyond the stricture, closed at one end, and having a small metallic connecting piece at the other, into which the injecting syringe may be screwed. This tube, by means of a slight coating of waxy composition, is, for the purpose of passing easily, rolled into the form of a common plaster bougie; and when it is not required to be of very small diameter in its collapsed state, the requisite stiffness may be given to it by rolling it upon a small catgut or stilet. A woven silk tube properly varnished would be perfectly water-tight; but this is of less importance, as a thick mucilaginous liquid will not escape but very slowly from a very imperfect tube made by sewing together the edges

of a riband. This instrument, which may be described as a dilatable bougie, is as durable, and may be made at as little expense, as any instrument used in the treatment of stricture.

FIG. 1. A dilator with a membranous distensible tube of greater diameter than the orifice of the urethra. It is injected by a syringe having a piston-rod in the form of a screw, which turns in a depression on the top of the piston. The syringe is connected with the metallic tube of the dilator by a flexible tube of material impervious to air, or any thick mucilaginous liquid injected with it.

FIG. 2. A dilator consisting of a long varnished silk tube closely rolled into the form of a bougie; there is a small screw at one end to connect it with a common injecting syringe of half an inch calibre, and the other is closed by several turns of strong silk, which may be secured by different obvious methods. When, for the purpose of rigidity, the silk tube is rolled upon catgut or metallic stilet, it is necessary that precautions be taken against these becoming loose in the passage; the catgut by some threads between its upper end and the tying of the silk on the screw, and the wire by being brought through the screw and bent. A piece of cord is represented in the figure tied loosely upon the upper part of the tube. This retains it in its compact form.

FIG. 3. A conducting tube from which a fluid dilator is seen protruding. It consists of a short silk tube rolled upon itself into less bulk than that of the smallest bougie, and tied upon the end of a narrow tin tube. When a long silk tube, imperfectly varnished, is passed through a conducting tube, this will, if narrower than the dilator in its distended state, prevent the escape of liquid from the part which it encloses.

In keeping up distension, by means of a dilator rendered impervious to fluid by gut or caoutchouc, instead of the stopcock recommended in former instructions on the subject, a contrivance may be employed for fixing the piston of the syringe, when the required degree of pressure has been made, as by a cord passing through the ring at the end of the piston rod, or by a screw. When the piston is depressed by a screw (which may constitute the piston rod) the patient can himself increase or moderate the pressure with the greatest facility. If the distensible tube be made of strong silk, it may be thus gradually distended until it becomes as hard as a cylinder of wood. A connecting flexible tube of silk and caoutchouc between the metallic part of the dilator and syringe, prevents any jerking motion of the instrument in the act of screwing on the syringe, and is a convenient index of the degree of pressure applied.

In other applications of the fluid dilator, as in the cure of stricture of the rectum, and in the operation of slowly dilating the male or female urethra for the extraction of calculi, a long connecting tube of this description, bringing the screw which regulates the pressure conveniently to the hand of the patient, would render the apparatus very complete. I have shewn, in the appendix to the late edition of my work on Stricture and Stone, that the advantage of *slow* dilatation of the male urethra must have frequently occurred to the operators by the Marian method, who professed to follow nature in their proceedings, as it has occurred independently to several surgeons of late years, (see MED. GAZETTE, Dec. 25, 1830); but that the want of any instrument which could fulfil the indication must have prevented the success of any attempt of the kind. The equable, elastic, and controllable nature of fluid pressure, makes a dilator, judiciously constructed on this principle, incomparably superior to any other means that has been employed for the purpose; and furnishes us with a method of extracting urinary calculi, which, if I am not much deceived, will soon supersede the present painful and dangerous operations.

When stricture is to be dilated beyond the diameter of the orifice of the urethra, it is necessary to modify the instru-

ment which has been described above. The distension may be confined to the diseased part by placing a wide silk tube within another shorter tube of smaller diameter, or by passing it through a wide silver or elastic tube previously inserted as far as the stricture. In cases of very narrow stricture, only admitting instruments of the smallest size, a dilator may be passed through such a conducting tube, consisting either of a single or double piece of narrow gut dried in a compressed form, or of a silk tube rolled upon itself, and rendered sufficiently rigid by means of thick mucilage. It is unnecessary in these cases to have a distensible tube of the whole length of the conductor; a small bit tied upon the end of a long flexible tin tube, connecting it with the syringe, is sufficient.

In mentioning this mode of conveying a small instrument to narrow strictures by means of a conducting tube, I am led to notice a controversy which has been continued through several late numbers of the MEDICAL GAZETTE, respecting the invention of what has been termed "the compound catheter." Dr. Buchanan, who claims the originality of this proposal, does not appear to be conversant with the modern French writers on urinary diseases, or he would have found that the plan of conducting small instruments through others of larger size is noticed in most of the works on that subject which have appeared in France during the last twenty years. But it is contended that Dr. Buchanan's instrument is more than a mere modification of former suggestions; that the principle of it extends further: the smaller instrument, it is said, is not only conducted, but a way is prepared for it through the stricture by the dilatation effected by the pressure of the ends of the outer canulæ. Had a reference been made to the work from which M. Ducamp borrowed so liberally, instead of the treatise of M. Gerdy, who in this matter professes merely to follow Ducamp, it would have been discovered that there is no greater novelty in this idea of previous dilatation than in that of conducting. In my Treatise on Stricture of the Urethra (p. 133, 2d edition) the following is mentioned amongst other means to be resorted to in cases of difficulty:—"The plan which I have recommended above, of

passing a large canula (which in this case has a rounded end) enclosing an instrument down to the stricture, is very applicable here; pushing the canula against the stricture opens it, while the small bougie or catheter within is ready to be passed through."

ON THE
STRUCTURE AND USES OF THE
LINGUALIS MUSCLE,

AND ITS RELATIONS TO THOSE OF THE
PANNICULUS CARNEUS.

By JAMES MERCER, M.D. F.R.C.S.E.

Lecturer on Anatomy and Physiology, Edinburgh.

[For the Medical Gazette.]

IN man, and some others in the higher classes of animals, the tongue seems to serve in the function of taste alone; and on investigating the structure and conditions of its upper surface in these animals, this function can alone be assigned to it.

In taking a review, however, of its uses, in the various classes of the vertebrata, we cannot be justified in considering it as only an organ of taste in all of these. Even in some of the highest classes—the ruminantia and the felinæ—it principally serves for the prehension and taking in of their food; and it is at least very doubtful whether it possesses the sense of taste in several others: although, on the contrary, we would not be warranted in denying the existence of this sense in these animals, nor even in such as are entirely destitute of the organ, as the function can be performed by other parts; it not being the effect of a special and limited organ, but a property of the mucous membrane lining the whole of the cavity of the fauces.

It has been long known, that in most of the herbivorous mammalia, particularly the ruminantia, independent of the epithelium, the dermo-mucous membrane covering the upper surface of the tongue is of very firm and dense texture, and that it forms, as it were, appendages to itself—what the hairs, bristles, and quills, are to the surface of the body; numerous strong pointed papillæ, imbricated on each other, in a direction from the tip to the base of the organ.

In many of the felinæ, the marsupiatæ,

and the bat tribe, the same peculiarity of structure takes place.

In several of the mammalia, the organ is not only used in the turning of the food from side to side, and for aiding in the primary part of the act of deglutition, but it also very materially, nay in some very essentially, aids in the collecting of the food; whilst it at the same time serves the purpose of a comb or rasp for the animal cleaning itself. The ox, for instance, with his free tongue, rolls the herbage of the meadow into a kind of tuft, before he tears it through with the lower incisors and palate; and he also rasps and cleans his own coat or that of his companion with its rough and prickly surface. In the dog and cat it is the sole agent, by means of which the fluids are conveyed to the mouth, by that action of the tongue called "lapping;" and, in short, in every animal using the organ in a similar manner, we have the papillæ on its upper surface correspondingly arranged and developed.

In all these animals also the muscular lamellæ of the lingualis are well developed, and very strong, immediately beneath the dense investing membrane of the tongue; and taking this fact, with the condition of the papillæ on its upper surface, with their evident mode of production and uses, it is curious that no other function should have been assigned to these muscles but that of "shortening the tongue and depressing its point,"—actions which we shall endeavour to show are only secondary, and the effect of another.

In the following remarks, therefore, we shall endeavour to point out more specifically what the real uses of these muscles may be; not only as these can be deduced from their anatomical arrangement and distribution, but also from analogical reasoning, in regard to their situation immediately beneath the epithelium and dermo-mucous covering of the tongue; serving to these structures, and their appendages, as we conceive, what the panniculus carnosus does to that of the cutaneous textures on the greater part of the surface of the body, viz. the erection or setting on end of these appendages, the papillæ.

The upper surface of the tongue in ruminating animals, and in the dog tribe, is covered over by a very dense

and almost cartilaginous membrane, extending from the epiglottis forwards to the tip, and over its sides, where it becomes much changed in its appearance and structure, and takes on the nature of true mucous membrane.

Along the median line it is much thicker, and more dense, than at any other part, and appears in the dog, in the form of a distinct and rounded cord, commonly called the "worm of the tongue." This, by Caldani, was called the "*linea albenscens**."

Posteriorly this membrane is intimately attached to that which extends between the base of the tongue generally, the epiglottis and the os hyoides, and, in structure, appears evidently to be similar to the yellow elastic tissue.

On making an oblique section of the entire thickness of this membrane, it appears to differ somewhat in its two anterior thirds from that which is seen in the posterior; and hence it has been looked on by Gerdy, as warranting two distinct terms—the "*membrane folliculaire ou muqueuse linguale*," and the "*tissu folliculaire linguale*."

The first of these, says he, "S'observe dans les deux tiers antérieurs de la membrane linguale, est grise, très-dense, fort résistante, cartilaginiforme, et comme si elle était tapissée par un lame cartilagineuse."

The second, the "tissu lingual folliculaire," est placé sous la muqueuse, très-mince de la partie supérieure de la base de la langue. Il occupe le tiers postérieur de la surface supérieure de celle-ci, environ tout l'espace qui est au-delà des papilles lenticulaires et coniques jusqu'à l'épiglotte, et on s'ouvrent les follicules si sensibles. Il adhère aussi très-fortement à la folliculeuse qui le recouvre immédiatement†."

This difference, however, appears to me to be more apparent than real; for, after the most careful examination of their minute structure in the ox and dog, no appreciable difference could be detected, and the only cognizable differences, the thickness and density, appearing rather to be dependent on the comparative absence of the papillæ on its upper surface.

On the two anterior thirds, where these projections most abound, there

the tissue is most dense and strong, and its sensibility less than in the posterior third, which is well known to be, next to the margins of the tongue, in the animals above specified, the situation where the sense of taste is most acute over the surface of the organ. This opinion is still more strengthened by a comparative examination of this investing membrane, with that which is found along and under the margins of the tongue. There the structure seems to be in every respect similar to the "*tissu folliculaire**."

Projecting from the upper surface of the whole of this investing membrane, we have a great number of papillæ, varying much in size, form, and arrangement. They are largest and most prominent in the middle and anterior thirds, particularly along the centre of each section, but more scattered along the margins. In their directions, when viewed laterally, and the tongue of the animal is kept in the bottom of the mouth, they appear to lie flat along the surface, but imbricated on each other from before backwards; their apices looking towards the epiglottis.

No sooner, however, is any sapid body, or any other stimulus, applied to the surface, than they are immediately elevated. When thus seen in the tongue of the dog or cat, they appear arranged in comparatively regular and transverse lines, the apices then being lifted up, and their posterior surfaces rendered concave, so that we have now a series of small channels, well adapted for containing and supporting fluids, placed in them, and thereby transporting them into the back of the mouth, during the pendent position in which the head of the animal is then placed.

In their structure, they are nearly similar to that of the investing membrane, and their adherent surfaces are intimately attached to the anterior extremities of the fibres of the superficial lingual muscles.

Immediately beneath this investing membrane, we find the irregular bands of muscular fibres, to which the term *lingualis* has been applied. These bands have been arranged by Gerdy into four sets—"the superficial and

* *Icones Anatomicæ*, Venet. 1804.

* See also Blandin, *Archives Gén. de Méd.*, 1823; also his *Thèse inaugurale sur la structure de la langue du bœuf*.

deep, the vertical and transverse lingual muscles*: but it is only the first of these which is the most conspicuous, and can alone act on the surface of the tongue and its papillæ. This muscle consists of two distinct lamellæ of fibres, extending from the base to the tip of the organ, and separated from each other by the *linea albescens*. In their general outline and configuration, they are slightly parabolic; their concavities looking towards each other along the median raphè, and their convexities to the margins of the tongue.

Posteriorly they arise by means of the glosso-epiglottic elastic tissue from the upper surface of the *os hyoides*, and from thence proceed forwards to different portions of the adherent surface of the investing membrane. The inner set of fibres are considerably the shortest; but they gradually become more lengthened as they are examined near the margins.

Their free or inserted extremities are undoubtedly into the whole of the lower surface of the investing membrane. This can be proved by two facts—first, by the roughened appearance of the dissection, after its most careful removal; this condition evidently depending on the severing of muscular fibres from it in their transverse direction; and secondly, from our inability to trace, even with a glass, any of the muscular fibres forming it, curving downwards to the base of the organ,—the general tendency of all the muscles of the tongue, the intrinsic and extrinsic, being towards its upper surface and tip. Immediately beneath these layers of muscular fibres, we find another layer of comparatively loose cellular tissue, surrounding the free extremities of the different muscles of the body of the tongue. This layer is very vascular, being freely supplied from the terminal branches of the lingual arteries. The chief use of this layer, as we conceive, being to enable the superficial lingual muscles to be freely and easily moved from before backwards over the surface of the tongue, unconnected and unrestrained by the influence of the other muscles, from which they are thereby completely separated. Analogously considered, it is similar in situation and use to the

adipose layer on the surface of the body, which separates the *panniculus carnosus* from those muscles which are in immediate connection with the trunk, and thereby confines its action to the common investing membrane and its appendages.

Having thus traced the fibres of the muscles, and seen that they are extended along the whole of the upper surface of the organ, and fixed posteriorly to the *os hyoides*, it will be easy to conceive that this latter must be the part whence it can become fixed before it can be called into action. Taking this, therefore, as its point of fixation whenever it contracts, either by the will of the animal, or by the presence of some stimulus, it becomes shortened in its length, and puckered, as it were, into transverse folds; and, it will also be observed, that, in consequence of the intimate attachment of the anterior fibres to the adherent surface of the investing membrane, this must also be shortened and wrinkled in a corresponding ratio.

No sooner, therefore, will this be effected, than its immediate free prolongations, the papillæ, will have their bases drawn backwards along with it, and with the natural consequence of lifting up and tilting forwards their apices; so that when the entire muscles are in a complete state of contraction, and the investing membrane shortened to its greatest possible condition, the whole of the papillæ on the dorsum of the tongue are raised up, and arranged, as already stated, in nearly regular undulating lines: serving thereby as so many tenter-hooks, for assisting in laying hold of the grass, in the herbivora; and forming so many hollow channels, or buckets, for lifting up, and containing safely—like the boxes of a circular chain-pump or dredging machine—the fluids, in such of the felinæ as take in this part of their food by the process of lapping.

The generally received opinion of the action of these muscles, viz. “of bending up the tip of the tongue,” can only, therefore, be a secondary effect, following the perfect evolution of the papillæ; but we doubt much if the muscles ever act in that manner, there being a sufficient number of more powerful muscles to perform it.

The situation, form, and uses of the *panniculus carnosus* are already per-

* *Recherches d'Anatomie, &c.* Paris, 1823, page 20.

fectly understood; and I shall therefore only allude to the great analogy that subsists between this muscle and the linguales now described. These latter muscles, the linguales, like the panniculus carnosus, are thin, broad, and lamellar; like it, it is also placed immediately beneath an investing membrane—that of the tongue, and intimately connected to it and its appendages; and, like that muscle, it is correspondingly developed where these appendages are large and well developed, and when the organ does not perform so much the office of a limited and special function; but rather that of a general kind. Is it not probable, therefore, that, its situation, connections, and varying peculiarities, being so strikingly similar, in its uses it will not also be similar?

ON STAMMERING,

AND THE METHODS PROPOSED FOR ITS
REMOVAL.

By EDWIN LEE, ESQ.

[Continued from p. 306.]

[For the *Medical Gazette*.]

FEMALES, it is well known, are much more affected by nervous disorders than men. Stammering, however, presents this peculiarity—that it is rarely met with in women or girls. Of the 100 cases mentioned in Mr. Yearsley's pamphlet, not more than three or four are females. Of 300, treated by M. Colombat, 286 were males, and only fourteen females. Of between thirty and forty stammerers who presented themselves at M. Amusat's, only three were women; and other statistical accounts represent the number to be equally small. This circumstance has never been satisfactorily accounted for, and perhaps the only rational explanation that can be given of it is, that women have naturally a finer organization of the parts concerned in speech, with a quicker apprehension, and that they think quicker than men; hence their articulation is more easy and fluent, they are capable of greater volubility, and experience less hesitation in speaking. This is even found to be the case at an early age. When children are required to appear and speak in public,

as on the stage, girls are almost always found to be best adapted for the purpose. How often do we not see a boy become confused, stammer, and hesitate, on being questioned upon particular subjects, and how seldom in comparison does this occur with girls of moderate intelligence*. Probably, if inquiry had been made of all the females who had presented themselves for the cure of stammering, it would have been ascertained that in several of them the infirmity had been acquired by imitation, as it must evidently have been with the two sisters mentioned by M. Magendie, who both stammered badly, and whose mother was also affected. This appeared likewise to be the case in a female whom I have recently seen, and whom I questioned upon this point. She, as well as her sister, thought her stammer was owing to her having been accustomed to go to school with another child who stammered. At all events, the circumstance of the comparative infrequency of stammering in females would be of itself a sufficient refutation of the opinion of those who regard this affection as dependent upon physical causes; as enlarged tonsils, and other anomalous appearances of the throat and tongue, are in all probability as commonly to be met with in the one sex as in the other. With respect to the comparative facility with which the majority of stammerers sing, it appears to depend partly upon the circumstance that the attention is concentrated upon keeping time and in the variations of the voice,

* "Little girls have the organs of speech more supple and flexible than boys; they speak sooner and easier, and women speak more agreeably than men. They are accused of speaking more: such ought to be the case, and I would willingly convert this reproach into praise. The eyes and the mouth have in them the same mobility. Always occupied in pleasing; observing, with the most persevering attention, every thing which passes around them; always expert to profit by their advantages; and reduced by the state of our society and manners, to shine only by singing, dancing, but especially by conversation, they give themselves up to these exercises with ardour, and excel in them more than men. The whole nervous system is also more developed in them; the impressions which they receive are more powerful and multiplied, and hence they have a greater number of sensations and internal feelings to make known; anxious to penetrate the secrets of men, and to ascertain the state of their hearts, speech is for them the most useful instrument, and the most indispensable to their happiness."—J. J. ROUSSEAU.

Here we have at once a rational explanation why stammering should be so rare, and other nervous affections so common, in females.

and partly that in singing the words run one into another more than in speaking, and the difficulties may be more easily eluded.

I will now briefly notice the opinions of some writers on the complaint, and the methods which have been proposed for its removal. The earliest instance on record of the cure of stammering is in the case of Demosthenes, who cured himself by reciting slowly, in a loud voice, long passages from the Greek poets, holding, at the same time, several pebbles in his mouth; and somewhat analogous methods have been found successful in more recent times. M. Itard proposed, in the year 1817, a sort of fork with two prongs, which carried the point of the tongue backwards, combined with the practice of speaking in a foreign language with which the person was not very conversant, by which means both the attention and the memory were exercised during the conversation; and it will generally be observed that stammerers, if required to read before strangers, will do so much better if they can take an interest in the book or paper presented to them. The attention being thus for the time diverted from the thought of their being observed. The plan of Itard, however, was not very successful: that of Mrs. Leigh, of New York, was more so, especially after the improvements of it by M. Malbouche, who introduced it into France. Mrs. Leigh considered that the difficulty of articulating depended on the circumstance of the tongue not being carried upwards, so as to touch the palate in speaking, she therefore made those under her care persevere in beginning each word by turning the tongue up to the palate; and between the years 1828 and 1830 had sent away from her establishment 150 persons cured. M. Malbouche superadded to this plan the drawing the lips backwards, so as to make the mouth appear larger, and when the phrase was terminated, the lips were again drawn back against the teeth, in order to recommence a fresh one. It was also required of the pupils to maintain a perfect silence between the interval of the exercises, and to practise declamation and reading aloud before attempting a familiar conversation, which was not permitted until the cure was considered to be effected.

M. Malbouche, however, divided

stammering into three kinds, according to the faulty positions of the tongue in speaking, and varied his method accordingly; but it would carry me too far to enter into the consideration of these varieties, which subsequent observation has shewn to be in great measure hypothetical. He says that the energy of the will is the most essential condition of success; and "that it is important to concentrate it exclusively upon the object to be obtained by the treatment. Children, and that class of men of the world who are accustomed to dissert upon and discuss every thing, without ever concluding upon any thing, are incapable of this concentration of the attention, and for that reason are difficult to cure: whereas experience has demonstrated that peasants, working men, and uneducated persons in general, are more easily cured. These individuals having but few ideas, seize with energy those which they can understand, and in which they are deeply interested." A want of confidence may cause any of the methods of treatment to fail altogether. In general those cures which are the most quickly effected are the least durable.

M. Serres divides stammering into two kinds: the first is characterized by a sort of St. Vitus' dance of the muscles concerned in articulation; the second by a tetanic stiffness of the muscles of the voice, and of respiration. In the first kind the will loses its influence over the rapid movements of the lips and tongue; in the second kind, the breath fails*. His method of treatment consists in making the sufferer breathe regularly, and combine his breathing with a certain cadence in speaking as in declamation and singing. Dupuytren likewise recommended stammerers to speak in a manner analogous to the recitative of operas, by which means much of the difficulty was obviated.

M. Rullier considers stammering to be a cerebral affection, and that it is attributable to some modification of the action of the brain. "But," says he, "in what does this modification consist? Without pretending to explain it, the following conjecture may be hazarded. In the stammerer, the cerebral irradiation which follows thought,

* *Mémorial des Hôpitaux du Midi*, 1829.

and becomes the principle which induces action in the muscles which are necessary for the expression of the ideas, rushes out with so much impetuosity, and is reproduced with so great a rapidity, that it exceeds the measure of the movements which are practicable by the agents employed in articulation. Hence, as if suffocated by this accumulation of the ordinary exciting cause of their movements, they fall into a state of spasmodic immobility, and of convulsive shocks, which characterize stammering*.

This hypothesis is, however, not borne out by observation. That there is a want of accordance between the cerebral action which occasions the muscular movements and the agents by which they are effected, will, I think, be clear to all who have paid any attention to the subject; and that this is the essential cause of stammering I have endeavoured to prove, as well as the manner in which it takes place. M. Magendie justly observes, in refutation of the above theory, "I have seen many stammerers; and if I have met with some in whom the degree of intelligence appeared to be very great, I have likewise seen others in whom time was not wanting to the muscles for the expression of the ideas, which were any thing but abundant or vivid. Stammering is evidently a modification of the contraction of the muscles concerned in speech; and since by means of physiology we can give no explanation of this contraction itself, how can we expect to explain its various degrees? Without occupying ourselves with researches which can lead to no useful result, let us limit ourselves to remarks on the kind of contraction of the muscles which take part in the formation of speech, and of which the action is more or less altered in stammering. M. Magendie then continues in the words which I have already quoted in the first part of this paper.

M. Colombat, whose work is the fullest and most recent on the subject†, regards stammering as a nervous affection, the principal character of which is a repetition by catches, or convulsive shocks, of a greater or less number of syllables; or a painful and temporary

suspension of the voice before some consonants or vowels which require a certain effort for their articulation. He divides the affection into two kinds, which he terms *labio-choreique*, and *gutturo-tétanic*. These are subdivided into several varieties. The first kind consists in a sort of chorea of the lips, and in a succession of movements, more or less rapid, of the tongue and lower jaw: it chiefly gives rise to disagreeable repetitions of b, b, b, t, t, d, d, d, or q, q, q. "In the second kind the stammerer remains with his mouth half open, incapable of producing any sound; sometimes, even when the word begins with a vowel, the face and neck become swollen, and the jugular veins distended. In some individuals the tetanic state predominates, in others the choreal, though the two kinds are not unfrequently united in the same person. Thus a stammerer in beginning to speak is stopped at the first word, if it commence with a consonant which is difficult to pronounce; then the fear of not succeeding renders the breathing hurried, and he becomes dumb, like a person affected with the second kind of stammer. In both kinds the stammering ceases by making a full inspiration; but it will soon return if the person do not take care to breathe regularly, and recurs more or less frequently, or with greater or less intensity, according as the breathing is more or less agitated, and according as the moral emotions which he experiences tend to increase or diminish the act of the will. "Now," continues the reviewer, "let us try to teach the stammerer to breathe regularly: let us connect his breathing with a certain cadence, as is the case in singing and declamation, the stammer will not occur; and if the individual can subject himself to the same constraint in conversation, he will be able to speak without stammering. To this result the method of treatment of M. Serres directly leads; whereas the other methods only attain it indirectly*."

It is foreign to my purpose to enter into the details of these educational methods of treatment: I therefore refer those who are particularly interested in the matter to the work of M. Colombat. In order to enable those under his care to keep, during their exercises, a regular

* Dictionnaire de Médecine: art. Bégaiement.

† Traité de tous les vices de la parole, et particulièrement du bégaiement, 2d vol. 3d edition, 1840.

* Gazette Médicale, 1840. p. 153.

measure, or cadence, in speaking, this gentleman makes his pupils use an instrument for counting, termed the *muthonome*, by which the rhythm may be accelerated, shortened, or kept at the same degree, at pleasure. After having enumerated several of the means which he employs, M. Colombat says, "The combination of the ortho-phonie means which have been described, constitutes a vocal exercise which has the advantage of acting at the same time physically and morally. It acts physically upon all the muscles of respiration; on the lungs, the larynx, and particularly on the glottis, on the tongue, and on the lips; in fact upon the entire vocal apparatus."

"It also acts morally. Thus the measure which exerts so beneficially its influence over all the organs, by regulating their movements, fixes the attention of the stammerers conjointly with the other parts of my curative method, and becomes an accessory idea, which, joined to the principal one, must necessarily place the nervous action which follows thought more in harmony with the relative mobility of all the vocal organs."

The following are the results which M. Colombat obtained from the year 1827 to 1833. Of three hundred stammerers treated at his institution, and in town practice, two hundred and thirty-two were cured without relapse, thirty-two relapsed, in fifteen the complaint returned after a second treatment, and twenty-one were incurable. The average duration of the treatment was twenty-five days. Two hundred and sixty-five were adults, twenty children under twelve years of age, and only fourteen women.

One of the worst cases of stammering which have fallen under my observation was that of a Savoyard boy, who presented himself at M. Amussat's. The difficulty in commencing most phrases was extreme, and the attempts were accompanied with strong spasmodic actions of the face, neck, and upper extremities. M. Colombat took him out of the room, and brought him back in about a quarter of an hour, when, by attending to the directions he had received, and keeping time by striking the fore-finger of his right hand against the left, he could articulate with much greater facility. The tongue and the muscles beneath it were

very much developed, and contracted strongly on the introduction of the finger into the mouth. The operation of dividing the genio-glossi muscles was performed, which produced a considerable amelioration, though it did not effect a perfect cure.

After an examination and comparison of the different methods of the educational treatment of stammering, M. M. Rullier and Itard remark that every measure which has been advantageously employed may be reduced to a sort of obstacle or moderator, which is opposed to the irregular, anormal, and embarrassed movements of the organs of speech. This moderator acts physically or materially; whether it be the pebbles employed by Demosthenes, the instrument for fixing the tongue of M. Colombat, or the fork of M. Itard. It acts also upon the tongue and other parts employed in articulation morally or mentally, by means of the attention, the will, the action of the memory, or the efforts at imitation. "The mechanism of speech," adds M. Itard, "is then performed under new conditions, associated as it is with certain voluntary movements, or with certain positions of the tongue, which are ordered, and which had previously been unconnected with the action of speaking. Such are the movements of the thumb upon the forefinger, or frequently repeated inspirations, as recommended by M. Colombat; the movements of the arm, as directed by M. Serres; and the different positions of the tongue, according to the precepts of Mrs. Leigh, and M. M. Malbouche and Colombat. Such are likewise the exercises of the memory, and of imitation, the difficulty the stammerer experiences in endeavouring to learn, and in speaking only in a foreign language, or to adopt, in his familiar conversation, the emphasis of theatrical declamation*."

[To be continued.]

CASES OF SUDDEN DEATH.

To the Editor of the Medical Gazette.

SIR,

IF you consider the annexed cases possess sufficient interest for the pages of

* Op. cit.

your valuable journal, they are quite at your service.—I am, sir,

Your obedient servant,
GEORGE DOWNES.

Stockport, April 23, 1841.

I was desired to visit William Smith, about 11 o'clock in the evening of April 5th, 1841: he had been attacked with faintness whilst talking with the housekeeper, sat down on a chair, put his head upon the edge of the dresser, and suddenly expired. I saw him in a few minutes after the seizure, and found him quite dead: his fellow-servants had placed him on his back on the floor, and were applying friction to his chest and extremities, and ammonia to the nostrils. The face, lips, skin, and conjunctivæ, were pale, and free from congestion. On the following day the body and head were carefully examined, but not the smallest vestige of disease was found in any of the viscera that could at all account for his death, except the heart, which was empty of blood. The right auricle was much dilated. The right ventricle was flabby in texture, and covered with a layer of fat. The valves were sound. A section of the arch of the aorta exposed incipient steatomatous and earthy concretions.

Remarks.—The subject of this case was 40 years of age, a butler, and a temperate liver, apparently in previous good health. I conceive that Mr. Chevalier's theory of a failure in the capillary circulation will not be tenable in this case: there was an entire absence of stagnation of the capillary, and of congestion of the larger blood-vessels and lungs. It is also evident that the immediate cause of death was not in consequence of respiration becoming imperfect, but probably the effect of syncope, resulting from a depressed state of the vital energy and circulation through the brain, by which the action of the heart was suddenly arrested. Spasm of the heart could not account for the absence of congestion in the lungs and great blood-vessels.

CASE II.—On the morning of the 17th of April, 1841, I was called to see Rebecca M'Ghee, a soldier's widow, of a spare habit of body, aged 62 years, who the night before had been drinking egged ale, and brandy and water, in the company of her daughter and two

others, at an adjoining public-house. She was intoxicated, but was able to walk home, where her daughter left her, to obtain a light from a neighbour: on her return she found her mother lying on the floor, perfectly insensible. She was assisted to bed, and in half an hour became sensible, so as to speak, and to get up to make water: she staggered, fell forward with her head upon the bed, and never spoke afterwards.

When seen next morning, she was lying on her back comatose, had a pale countenance, soft pulse, cold surface, contracted pupils, and stertorous breathing. She was cupped. Enemata and sinapisms were administered; and, in the afternoon, six or seven ounces of blood were drawn from the arm. The pulse sunk during the operation, and the symptoms continued unabated till her death, on the morning of the 19th instant.

On dissecting back the scalp, an ecchymosis was seen, the size of a half-crown piece in the centre, and above the occipital tubercle; and, on removing the calvarium, a coagulum of four ounces was found between the dura mater and arachnoid covering the right hemisphere of the brain. There was no laceration of its substance, nor was it possible to trace the source whence the extravasation had proceeded. Query?—did the effusion of blood arise from violence, or from natural disease? It is highly probable that the internal hæmorrhage in this case arose in consequence of the excitement from intoxication, and of the morbid predisposition to it from frequent attacks of headache and drowsiness; that the effusion took place when she first fell down, and gradually increased, so as to prove fatal by impairing respiration.

CASE OF OTITIS,

COMPLICATED WITH CEREBRAL DISEASE.

To the Editor of the Medical Gazette.

SIR,
SHOULD the following case appear worthy of a place in your journal, it is very much at your service.—I am, sir,

Your obedient servant.

GEORGE FIFE, M.D.

Newcastle-upon-Tyne,
May 11th, 1841.

E. T., æt. two years and three months, had for some time seemed unwell, being very listless, feeble, and drowsy. This last symptom existed to such a degree as to cause her frequently to fall asleep during the day, even when in the sitting posture. When walking across the floor she appeared for some weeks afraid to step out, and to have difficulty in maintaining the erect position. This was at one time, by her parents, ascribed to shoes hurting her feet. I, however, apprehended some spinal cause; but, on the most careful examination, could detect nothing corroborative of such opinion. The bowels had been irregular and disordered for some time, in consequence of which occasional alteratives and aperients were given. After continuing for some weeks in this state, and complaining of pain in her left ear, it gave exit to a fetid, muco-sanguinolent discharge, manifestly attended with temporary relief. This was of short duration, as head symptoms became too prominent to leave any doubt as to the sensorium being implicated. Strabismus, convulsions, and coma, now took place, and continued till death put a period to her sufferings. It is enough to say, that the ordinary remedial measures, as leeches, blisters to the nape of the neck, calomel, turpentine enemata, and cold to the shaven scalp, were assiduously employed.

Autopsy.—Development of head peculiarly good; scalp attenuated and exsanguineous. Bony parietes thin. Dura mater perfectly healthy; the venous trunks engorged. There were very strong adhesions, over the left ear, between this membrane and the arachnoid, which on the right side was nearly natural; whilst on the left it was highly vascular, with some slight adhesions between it and the dura mater, near the longitudinal sinus. Pia mater free from any morbid appearance. Considerable serous effusion about the base of the brain. The substance of the brain, on a horizontal section being made, was found quite healthy. Serous effusion in considerable quantity in both ventricles. Foramen of Monro inordinately large, being capable of affording transit to the largest goose-quill. Slight softening of the anterior lobes of the brain, especially the right. Plexus choroides unusually pale and flaccid, exhibiting no sign of congestion. On examining the

petrous portion of the left temporal bone, it was found very soft, being easily penetrated by the point of a scalpel, but without any appearance of caries, or separation of its membranous covering. On being sawn into, the internal ear and cells were filled with pus, which exuded abundantly so soon as the saw penetrated the cellular structure. For the above very accurate examination I am indebted to my friends, Mr. Potter and Mr. Maugham, by whom the dissection was most carefully conducted, and who, at the time, regarded, along with me, the case as an excellent illustration of the complication of otitis with cerebral disease; in which opinion we conceived ourselves borne out by MM. Itard and Rostan.

Reflection on this case suggests an interesting and, in a practical point of view, not unimportant question; viz. was the disease primarily in the ear, and the brain, &c. implicated merely in a secondary manner; or was the brain primarily affected, and the ear ultimately took on the inflammatory action? This question is difficult of decision; but one which is well deserving of consideration. I shall now offer a few very brief remarks upon it.

That the complication is of common occurrence there can be no question with any practical man, who has had much to do with the care of infantile patients. At the same time candour will compel him to acknowledge, that in no case can it be more difficult to distinguish cause and effect: this, at least, is the result of a tolerably extensive practice in such cases with me. The supposition of the primary disease being in the ear is favoured by the following circumstances. The child, at an early period, complained of pain in the ear, which was soon followed by suppuration; and from which, at the time, relief was evidently experienced. The principal indications of disease, as met with on dissection, were also found on the left side. On the subject of the extension of disease of the ear to the brain and its membranes, I cannot do better than make the following brief quotation from M. Rostan, who, speaking of otitis, says, "*Elle peut se propager jusqu'aux méninges et à l'encéphale; alors les symptômes des phlegmasies de ces organes se joignent à l'otite.*" The idea that the disease originated in the brain is favoured by

the fact that the child had been evidently out of health, with loss of appetite, deranged bowels, &c. for some weeks before it made any complaint of the ear; which, it must be well known, is a condition which very often precedes the unequivocal indications of cerebral disease, more especially that form of hydrocephalus to which the term *chronic* is not perhaps justly applicable, but which is *de facto* subacute. That, in these cases, the ear is often affected, I can testify from personal observation; and am happy in being able to corroborate this by again referring to M. Rostan, as the following passage sufficiently proves. "D'autres fois les maladies cérébrales commencent, et l'otite n'est qu'un effet consécutif. La mort peut alors terminer cette affection." The same writer, under the head of chronic hydrocephalus, gives the following emphatic description of symptoms, and which is but too graphic, so far as the present case is concerned, in its early stage. "Les sens sont d'abord affaiblis, l'intelligence est presque nulle, la mémoire abolie; il existe une grande indifférence, la marche est chancelante, quelquefois impossible. La malade éprouve souvent de la somnolence," &c. &c.

In conclusion it may be observed, that whatever the primary seat of disease was in the case before us, extreme vigilance on the part of the physician is required to detect the very first appearance of cerebral symptoms, and to use every means calculated to oppose their assault; as even where such symptoms are not present, it is often useful to apply a few leeches and blisters in such a way as to affect the nervous centre.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégier."—D'ALEMBERT.

Hints for Invalids about to visit Naples; being a Sketch of the medical Topography of that City. Also an Account of the Mineral Waters of the Bay of Naples, &c. With Engravings. By J. C. Cox, M.D., &c. London, Paris, and Nottingham, 1841. 8vo. pp. 190.

THE chief subjects treated of in this work are the medical topography of

Naples; the question whether Naples is a good winter's residence; the mineral waters of Naples and its neighbourhood; the mineral and thermal water of Pozzuoli; Ischia and its hot springs; and the mineral waters of Castellamare and Torre del Annunziata. When discussing the medical topography of Naples, Dr. Cox gives the following hints:—

"1. That the apartments for an invalid should have a southern aspect: this is quite essential throughout Italy. A south room, at Naples, has the sun in winter, and receives the sea-breeze in summer. There is sometimes a difference of from 30 to 40° of Fahrenheit between the north and south side of a house at noon; and in a room with a south aspect, the thermometer will rarely fall below 60° throughout the winter, even without fires. During the night there is but little difference.

2. None of the apartments should be exposed to the Tramontana winds, or N.E.

3. The apartments should not be too near the Tufa rock, through which the offensive fluids from the drains often percolate, causing unpleasant and unwholesome effluvia."—p. 27-8.

The months of October, November, and December, are generally mild and pleasant, the mean temperature of these months being respectively, 62°, 55°, and 51°; in January (the coldest month) it is 45°.

Dr. Cox cautions the invalid against leaving Italy too early in the spring. In 1839, he left Naples, in charge of an invalid, on the 4th of April, when the weather was deliciously warm: the Judas tree was in blossom in the Villa Reale, and nightingales were singing in the Pontine marshes. On the 6th, however, it was cold at Rome; and though it was warm on the 14th at Bologna, he passed the Alps in a snow storm on the 23d.

Naples and its neighbourhood possess mineral waters of high repute. The Acqua de' Pisciarelli is a very remarkable one. A pint of it contains nearly 22 grains of acid sulphate of alumina; five of sulphate of iron; and twelve of sulphate of lime; besides seven grains of "free sulphuric or sulphurous acid."

Dr. Cox's book contains very useful hints, both for invalid and physician.

Medicinische Fragmente betreffend eine allgemeine Lehre des Seebadens und der Seebäder, und die Identitätsfrage der Kuhpocken und Menschenpocken. Von DR. CARL MÜHRY, u. s. w. Herausgegeben mit einigen Zusätzen von DR. ADOLPH MÜHRY, u. s. w.

Medical Fragments relating to a general system of sea-bathing and sea baths, and the question of the identity of cow-pox and small-pox. By DR. CHARLES MÜHRY. Edited, with some additions, by DR. ADOLPHUS MÜHRY. Hanover, 1841. 12mo. pp. 168.

DR. CHARLES MÜHRY, whose life, too short for science and his friends, terminated at the age of thirty-four, was court-physician at Hanover, and official physician (*Badearzt*) at Norderney. This is a sea-bathing place on the German Ocean, and his appointment there excited Dr. Mühry to visit a number of similar spots in the autumn and winter of 1839-40, in order to compare their respective advantages. He visited Scheveningen, Ostend, Dunkirk, Calais, Boulogne, Dieppe, Havre, Barmouth, Aberystwith, Tenby, Plymouth, Torquay, Dawlish, Weymouth, Brighton, &c.: but his health, previously feeble, sank under the hardships of such a tour at such a season, and he died in March, 1840.

These fragments make us regret that his career was so brief; for Dr. Mühry was evidently a man of talent as well as of industry.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

THE STATE OF THE PROFESSION.

AMONG the numerous letters which we have received on the subject of Medical Reform, none more plainly points out the origin of the great mass of evils which now press upon the members of our profession, than that published last

week under the signature of J. R. B., in which they are described as arising mainly from the superfluity of practitioners—from the "overstocked medical market," as the writer calls it. Our correspondent evidently writes from a practical knowledge of the subject; and we are glad to have received a confirmation of the opinions which we have often advocated from so respectable an authority.

Look where we will, we find illustrations of the same fact, that the supply of medical men of all classes is greater than the demand for them, or if not greater than the demand, yet certainly greater than is proportionate to the means, or the disposition, of the public to remunerate them. In those positions which are deemed the highest in the profession, and which have at all times required either the greatest amount of talent or industry, or else the most fortunate concurrence of external circumstances for their attainment, how great is now the disproportion between the number of candidates and that of the places that can be found for them! It is but a few years since physicians were *invited* to take high stations in great hospitals; and a young man had but to attach himself to a hospital, in order to be sure of arriving in a few years, with little or no opposition, at some honourable and profitable post in it. Such was the case with the majority of the elders among our present hospital physicians and surgeons; they obtained their office as a matter of course, with little trouble, or with, at most, the exercise of a few years' patience: the reputation which they had acquired for talent or industry, or their good connection, was sufficient to displace the few and unimportant competitors for office. But now, how different is the case! Not only do offices of value become vacant less frequently, but, when vacant, there is

not one that is not contended for by a number of candidates—all, it may be, of high merit, and all bringing forward powerful personal claims. We may safely say that there is not now a hospital in the metropolis, or in the provinces, but has at least three candidates for the next office that may fall vacant, be it what it may; and in many the number of expectants is yet much larger: so that in general he who determines on entering upon this high ground of medical practice may reasonably anticipate that he will have to wait not less than a dozen years before his time for election will arrive; and unless he is most favourably placed by personal connection (a kind of influence of which the value is now rapidly decreasing) he must be content to maintain his claim for even this distant privilege by constant and intense application to his studies.

Such, we believe, is strictly the case with the aspirants for the highest advantages and honours which are to be found in the medical offices in our large hospitals. If we descend a step, and look at the state of the smaller institutions and the dispensaries, the case is the same, but the competition is yet greater. And this is the more remarkable when it is considered how small, how insignificant, an amount of advantage is to be obtained from a connection with these minor institutions, the majority of which offer neither direct nor indirect remuneration of any kind whatever. Yet, in spite of this, no office even in them falls vacant, but it is earnestly contested for: the little amount of fame that may result from publishing one's name in a legitimate advertisement, the imagined connection to which it may lead, the erroneously anticipated advantage of possessing a title of any sort, and the necessity of doing something to maintain one's knowledge and one's spirits,—these are

sufficient reasons for incurring expense, labour, and responsibility. Nay, more than this, so great is the anxiety for the little opportunities which dispensaries offer to young practitioners for raising themselves above the mass, that they are often *got up* for this only purpose; the relief of the sick poor being merely an end which they accidentally fulfil. And what is worse, they are got up not always by the exertions of the intended medical officers, but sometimes even at the expense of those officers themselves. It is but a few months since we heard it mentioned with much satisfaction, that the poor of a certain district were likely to obtain considerable advantage from the establishment of a new medical charity there; for that two young practitioners had promised to contribute each a thousand pounds towards its funds on the (*implied*) condition that they were to be the medical officers.

The case is nearly the same with the still lower medical offices; surgeoncies to Unions and parish-workhouses are urgently canvassed for, the contract system is humbly submitted to, and gentlemen by birth and education are obliged to allow themselves to be treated like little tradesmen by their inferiors, in order to obtain what seems to afford the only chance of a decent maintenance,—the reputation of conducting a practice. And if we pass from the endeavours to obtain public offices, for the sake of the private practice to which they are (often unwisely) expected to lead, to the events of private practice itself, the competition only becomes more severe in direct proportion as the stake contended for is more palpably valuable, and more immediately at hand. It would be too long to tell even a brief tale from our own knowledge of it; let our readers look again over our correspondent's letter; he is one of themselves, and he has told them plainly enough their dis-

order, though he may not have suggested the right remedy; let them see if what he has described be not as true, as it is a vivid picture of what may be seen every day in our profession. The simplest statement of the case is, that a maintenance must be had by all; those on whom the necessity falls most heavily cannot afford to be very nice or etiquette about the means of obtaining it, so they be but honest: and each, "in his fall, drags down with him the whole profession:" few or none can afford to have their whole practice taken from them, and all, therefore, descend a step or two that they may adapt themselves to the disposition of the public, whose eye is as keen to the price of medical attendance as to that of any other article, and who, when the charges of the practitioners are different, can easily persuade themselves that all the *cætera* are *paria*, and find a good excuse for employing the cheapest.

Now this is an evil not capable of remedy by any of those schemes of medical reform that are so fondly and so loudly agitated: it is absurd to charge this upon errors of medical government, or to regard it as any thing but the natural result of our profession having, not long since, offered at a low price such advantages, both pecuniary and social, that more were induced to enter it than it can honourably maintain. Add to this, that the want of power to prevent the practice of unlicensed men has enabled the whole multitude of chemists and druggists and charlatans to come into open competition with the legitimate practitioners of every branch of the art, and the fundamental source of the evil condition of the medical profession is easily explained.

Would that its remedy were as easy, and that it could be effected without much endurance of hardship and annoyance by those whose lot has

fallen in these evil times! Still, it is some comfort to know that the natural remedy is working, and that if the remuneration of medical services cannot be raised sufficiently to keep pace with the increased number of those who claim a maintenance for them, the number of claimants is slowly, but certainly, decreasing; and that in the course of some few years it may reasonably be hoped that it will be reduced to such a number as may find enough to serve them all. At the commencement of the winter season we pointed out the fact of the general decrease of the number of students who had arrived in London for the completion of their medical studies. At that time we stated it as our opinion, that the increased facilities of education in the provincial schools, to which the decreased number of students in London was generally ascribed, were not sufficient to account for more than a small part of the great deficiency at that time evident. And our opinion is fully confirmed, by the fact that the provincial schools have all, or very nearly all, suffered decrease in the number of their students, at the same time, and in the same or a greater proportion, than the London schools have. Add this to the fact, which must be familiar to every provincial practitioner, that the number of pupils apprenticed in each town without a medical school is considerably less than it was ten and twenty years ago, although the number of surgeons is considerably greater, and no further evidence can be needed, that the number of practitioners of every class will, in a few years, be greatly diminished, if not absolutely, at least proportionally to the increasing population and means of remuneration.

But meantime inconveniences must be felt, and upon some must fall heavily. Yet it behoves all to consider how they may in some measure relieve themselves; and there can be little

doubt that they will best do this by taking the highest ground they can; by avoiding, as far as possible, all those plans of gaining money or repute which they feel to be derogatory, and by enduring even a limited remuneration patiently, rather than seek a competency by practice which is dishonourable to their profession. The misfortune is, that the public, finding the hold they have upon the medical man—that by the competition he has to encounter he is often driven to his last resources, and compelled to be content with almost any terms that afford him a prospect, however distant, of bettering his condition—take advantage of him; and, in the ordinary fashion of the day, grind him down. Hence it is that public offices once paid are now sometimes required even to be paid for; hence that in charities, and almost all other institutions, the only officers not paid, or inadequately paid, are the physicians and surgeons, who have to look on calmly and unprofitably, while solicitors, agents, architects, and collectors, are drawing handsome incomes from the sources on which *they* gratuitously attend. Hence, too, it is, that shillings, or nothing, are offered for vaccination; that medical services, like butcher's meat, and flour, are to be tendered for; and that when a practitioner would give his gratuitous services in the cause of charity, he must ask leave, as a great favour, and incur what are regarded as deep obligations by those who give their votes in his favour.

The fact is, that though, on the one hand, there are certainly more practitioners than the public can be reasonably expected to remunerate: yet, on the other, the public are not made to give nearly so much of either respect or money to the medical man as they can well afford. And the only mode in which they can be made to do so, is by force. However

much the legitimate practitioner may suffer at the first by refusing to do what he honestly regards as dirty work, he may rely on it that in the long run he will be repaid for his honesty: his services cannot be dispensed with; he may proceed upon it as upon a certainty that good medical attendance will at last be paid for at any price, and that if he can but wait he must in the end get his own terms. This belief is the best guide that we can offer for overcoming all the hydra-evils that spring from the present superfluity of medical practitioners: they are indeed but temporary; but they are for the time so heavy that any relief from them ought gladly to be made available.

MEDICAL REFORM.

RECENT PROCEEDINGS OF THE COLLEGE OF PHYSICIANS.

To the Editor of the Medical Gazette.

SIR,

MY attention has been called to an editorial article in a late number of the *Lancet* (for May 8), purporting to give to the readers of that periodical some account of the more recent proceedings of the College of Physicians in regard to medical reform. The true spirit of the *Lancet* has never shone forth more conspicuously than in those few pages. The aim and object of the article is to traduce a certain portion of the College, namely, those *petitioning Licentiates*, who have within the last five or six years been elected into the fellowship. These gentlemen have incurred the high displeasure of the governing powers at the *Lancet* office, in that they accepted the hand of good fellowship held out to them, and have lent their aid to reform abuses, instead of holding back to participate in the work of destruction. These are heavy crimes in the eyes of the *Lancet*, and such men must be held up to public contumely lest their conduct should become contagious. The *Lancet* evidently dreads the labours of those who set themselves seriously to the repair of a time-worn edifice. For years past it has been struggling to pull down, in the hopes of erecting, on the ruins of

the old medical corporations, a new order of things, which shall be perfection unimprovable: in plain English—a medical parliament, with the Lancet as Speaker.

To have looked to the Lancet for a simple statement of the events that have recently occurred within the walls of the College—to have anticipated in its pages a candid acknowledgment of the difficulties to be overcome—to have expected that its columns would have attributed honourable motives to those who took the lead in the discussions, and have acknowledged in their efforts a zeal for the welfare and honour of the profession; this would indeed have been to have hoped to gather grapes from thorns, and figs from thistles. Far different is the course of the Lancet. That moral obliquity of perception which has distinguished its career throughout, could see only in the efforts of the petitioning Licentiates “an abandonment of the principles for which they originally contended,” and an ardour in the upholding of injustice “which might have deceived the very elect.”

It is high time, sir, that the profession at large should be set right on these points. I feel assured that the great bulk of the profession throughout this country are willing to listen to the truth when it is set before them, and take more pleasure in a plain unvarnished tale than in the distortion of some facts, and the concealment of others. I do them only common justice, when I attribute to them no wish to misrepresent either the motives or actions of those who are engaged in the business of repairing the defects of the old medical corporations, and adapting them to the spirit of the age in which we live. To such men I now address myself; and I feel persuaded they will bear with me while I state, as briefly as the extent and importance of the subject allows, the principal points which have lately been under discussion at the meetings of the College, and the practical results to which those discussions have led.

The first sketch for the improvement of the College of Physicians has been for some time before the public. After enumerating the several grievances alleged by the petitioners for medical reform, it proceeded to suggest a va-

riety of measures calculated to obviate these objections, and to meet the wishes of the great body of physicians scattered throughout the country. The College of Physicians virtually acknowledged, by sanctioning the publication of their Committee's report, that the altered circumstances of the times demanded great and important changes in their constitution. Some of the projected alterations had reference to the interior economy of the corporation, contemplating more especially the relation in which the Fellows and Licentiates should hereafter stand towards each other. Others had reference to the relation which might hereafter advantageously subsist between the Members of the College of Physicians of London, and those of the Colleges of the sister kingdoms. The matter brought under discussion involved both principles and details. It was felt to be more imperative on the College to lay down general principles than to suggest measures of detail. It was considered also, but not until after ample deliberation, that it would conduce to a better end, and work out more practical benefit to the profession, if the College of Physicians confined its recommendations, in the first instance, to the improvement of its interior economy, thereby giving an earnest of its readiness to assist more largely afterwards in the great work of medical reform.

The first question, then, was, how should the Licentiates stand in regard to the Fellows, keeping in view the general interests of the profession? It was agreed on all hands, that the term *Licentiate* should be abolished, and that of *Member* substituted. To prove that this change was not in name only, it was further agreed that the Members or Licentiates should have access to the library and museum of the College. It was next proposed to endow them with certain substantive powers. The original idea was to grant to them the exclusive right of initiating all successions to the fellowship, reserving to the existing Fellows the right of veto upon one half of their nominations. This proposal having been objected to, it was then agreed that Fellows and Licentiates should have an *equal* right of voting at the election of Fellows, and that all Members, of whatever standing, should be eligible to the Fellowship.

But it was felt that a bond of union

between the Fellows and Members was still wanting. To supply this deficiency, it was proposed, and agreed to, that once in every year the Fellows and Licentiates (or Members) should meet together at a general conference or concio, when Fellows should be elected (by ballot), and such other business transacted as might hereafter be agreed upon. To prove the anxiety of the College to act *bonâ fide* in these matters, and to give, not the semblance but the substance of corporate improvement to the great body of physicians practising in this country, it was then agreed, that all physicians now practising throughout England and Wales with a diploma of M.D., obtained, after examination, from any British University, should be entitled to admission as a Member of the College without examination, provided application should be made within twelve months from the passing of any new act or ordinance for the regulation of the College of Physicians; and that, at the expiration of such year of grace, the list of Fellows should be augmented by about one-fourth of their existing number.

In the progress of the discussions on those points, it was, as the *Lancet* stated, proposed by certain members of the College, that the order of Licentiates should be abolished altogether. This proposal was objected to, on the ground that it was desirable to uphold reasonable objects of ambition to the physician at all periods of his career. His first object would be, after acquiring academical honours, to become Member of the College of Physicians, then Fellow, then one of the Consiliarii; reserving, as the highest object of ambition, in his maturer years, the dignity of President. The *Lancet* misrepresents the petitioning Licentiates, when it avers or implies that they contended for an absolute equality of privileges between the orders of Licentiate and Fellow. Their complaint was, that the graduates of Oxford and Cambridge claimed admission to the Fellowship as a right, while graduates of other Universities (including, *ex necessitate rei*, all Dissenters) were excluded from making such a claim. This was the master-grievance of the petitioning Licentiates. They never prayed that the distinction of Fellows and Licentiates should cease, but that the distinction as to admission to the

Fellowship, founded on the locality where the diploma had been received, should thenceforth cease and determine. Greatly is it to be regretted that the prayer of that petition was not then (1833) freely and unconditionally granted by the College. Had such a course been taken, I am strangely deceived if the march of medical reform had not then advanced, slowly but steadily, and the world been spared that sad display of jarring interests and contending factions which the medical profession presents at the present moment.

On the desirableness of amalgamating into one College or Commonalty all the practising physicians throughout England and Wales, and of giving to them all one common interest, the College of Physicians is now agreed. They have come to the determination of recommending measures which will, I sincerely believe, contribute to that most desirable consummation. They are willing to go further, and in the same spirit to discuss with the government, and the other corporate bodies, such measures as may be necessary to establish a proper relation between the practising physicians of this and the sister kingdoms; to organize a council of revision; and to secure, by proper enactments, a due amount of elementary medical and scientific education.

While the College is proceeding in this just and honourable course, let the readers of the *Lancet* hesitate ere they give credence to the stories they may hear of renegade Licentiates, and their abandonment of principle. The cause they have at heart, the improvement of the medical profession, will, I am persuaded, be better served by ample deliberation, and the careful improvement of existing institutions, than by the adoption of untried schemes, and the substitution of a visionary simplicity, inapplicable to the varied state of society in the different portions of this extended empire. To co-operate with their fellow members of the College of Physicians in attaining such an object, will be, as it has been, the constant aim of the petitioning Licentiates, in spite of all the sarcasms of the *Lancet*.—I am, sir,

Your obedient servant,

PHILODEMUS.

London, May 18, 1841.

DR. WILLIAMS in the Chair.

Colica Pictorum treated with Warm Water.

By JOHN WILSON, M.D. Physician to the Middlesex Hospital.

IN this paper, the author, after referring to the complicated treatment of the disease pursued at the hospital of La Charité, proposes to illustrate two of the remedies there used, in combination, namely, enemata and hot baths.

In six cases of colica pictorum, some of them of much severity, and complicated with paralysis, Dr. Wilson has employed enemata administered in the hot-bath, in one case by the patient himself, and consisting of the water of the bath. The effect of this combination has been very successful, both in regard to the symptoms of pain and constipation, and to the paralysis where that existed. In the course of his statement the author notices the presence of looseness of the gums, blueness at their edges, and a factor like that of mercury, where none had been taken; and informs us that he has noticed this latter circumstance in other cases of colica pictorum.

He next details a case of constipation not attributable to lead, in which the above remedies had proved equally successful. In some of the above cases this treatment is used alone; in others it is followed up by doses of pil. saponis e. opio, of oleum ricini, with tinctura opii, or with a solution of sulphate of magnesia and carbonate of magnesia in mint water.

The President said that the method of treating the disease at La Charité, to which the author had alluded, had long been proved in this country to be unnecessarily complicated and severe. At St. Thomas's Hospital it was always found that the disease would yield to the administration of purgatives of almost any kind, combined with opiates. He believed the only novelty in the present paper was the recommendation that the warm water enema should be administered in the bath, and that the patient should be allowed to discharge his feces there also.

Dr. Mayo said he feared that, by omitting the greater part of the author's histories of cases, he had not acquired for the method of treatment recommended in them all the credit that it deserved. He was bound, therefore, to say, that it had been very successful even in cases of great severity.

A paper was afterwards read—

On the Results of Amputations performed at the North London Hospital. By Mr. POTTER. Communicated by Mr. LISTON.

Mr. Perry said he should like to ask of Mr. Liston whether the exactly transverse manner in which the limb was described as being transfixed, in forming the flaps, had been adopted in order to avoid the oblique division of the femoral artery, which had been stated as one of the objections against the flap amputations of the thigh. In many cases that he had witnessed of the ordinary flap amputations, the artery had always been very obliquely divided, so that it could be tied only with considerably greater difficulty than in circular amputations.

Mr. Liston said that the formation of antero-posterior flaps was adopted without any reference to the mode in which the femoral artery was divided. It had considerable advantages in securing the stump from the protrusion of the bone, which was very likely to take place after amputations with lateral flaps. In them there was nothing left by which the action of the psoas and iliacus muscles could be prevented from pulling the thigh upwards towards the abdomen; nor could any artificial means be adopted to prevent this, especially in children; and its consequence very frequently was, that the sawn end of the bone was so drawn up as to protrude at the anterior angle of the wound. The antero-posterior flaps permitted no inconvenience of this kind. As to the oblique division of the femoral artery, he did not consider that a matter of any importance; it was easy enough to dissect its cut extremity a little backwards with the amputating knife, and apply the ligature quite above the division, however oblique it might be.

Mr. Rutherford Alcock said that the question of amputations generally, and of the different modes of performing them, and of the effects of different circumstances upon the results of the cases, had engaged much of his attention for several years. Many of the results which he had attained were already before the public, and he would now limit himself to observations on the principal topics of the present paper, and especially to the question of the comparative advantages of the flap and circular modes of operation, and the results of each with reference to the ultimate terminations of the cases, and the several accidents that supervene on amputations. With respect to the occurrence of secondary hæmorrhage, he quite agreed with Mr. Liston that the oblique division of the femoral artery was not a matter of importance. But he was not sure that the oblique division of the smaller arteries had not some influence in bringing on or permitting that accident. He had often thought

that, in flap amputations, the small vessels retracted only partially, which, in circular amputations, would have retracted completely; or that the vessels in the former case were overlooked, which, in the latter, bleeding distinctly, would have been secured. Nothing, however, had convinced him more of the necessity of having accurate records of series of cases, and of not trusting to general impressions, than the results of amputations. In these questions, more than in any others, general impressions were apt to be erroneous, from the circumstance of the strength of the impression which single events, deemed at the time remarkable or important, make upon the mind. With respect to this very question of secondary hæmorrhage, for instance, he had himself gained a very wrong impression from two cases, which was not corrected till he had accurately ascertained the results of the whole series of those that had fallen under his observation. The two cases were these:—In an epidemic from which the troops under his charge suffered at Vittoria, the legs in several cases became gangrenous, and required amputation. In the first two instances he amputated in each patient one leg by the flap, and the other by the circular operation; and in both these cases the flap operation was followed by secondary hæmorrhage; but after the circular none supervened. The circumstance made such an impression on him that he entertained no doubt that flap amputations were more obnoxious to secondary hæmorrhage than circular, till he came to sum up the results of all his cases, or, at least, of all those of which he had a regular and well-kept series. The result of this examination was, that in 115 cases, of which 90 were circular amputations, and 25 flap amputations, the proportion of secondary hæmorrhages was somewhat greater in the former than in the latter. In the second place, with regard to the liability to necrosis of the sawn bone in the two classes of cases, he did not think that any difference could be found between them: and it was the same with regard to the conical form of the stump, an event which he believed could only very rarely occur after either kind of amputation, if dexterously performed by a surgeon practised in the operation. As in the 115 cases alluded to it had occurred only twice, he could not draw any conclusion respecting its frequency in one or the other operation. With reference to the main question of the comparative mortalities of each mode of operation, he has found that his results were by a fraction disadvantageous to the flap amputations. He was not, therefore, prepared to agree in what was said to be the growing opinion that this operation would in time completely supersede the other. It was true that the flap amputation was a

more rapid mode of operating than the circular, and to this full weight must be allowed; for pain is in itself an absorbent of life, and is always followed by a reaction and a febrile disturbance, that may have an important influence on the recovery of the patient. At the same time he thought that the difference in this respect between the two modes of operation had been overrated. Eighty or ninety seconds were ordinarily sufficient for the performance of the circular operation; and if the flap amputation were done in fifty or sixty, the difference of the times during which the patient was in each exposed to pain was really not so great that much importance could be attributed to it. It did not appear to him, therefore, that on this ground there could be any just reason for discarding the circular mode of operation. A more important point seemed to him to be involved in the question of the after treatment of the stump. There was nothing of which he was more certain than that the idea of the advantages of union by the first intention, which was so commonly held in this country, was greatly exaggerated, and he would go so far as to say that, in some cases, such a union was not only of no advantage, but was actually mischievous, and dangerous to the life of the patient. For patients, after immediate union of the wound, would often, as he had himself seen, die of the very diseases which were said to result from the wound remaining open. In a primary amputation, after an accident in a healthy man, it was no doubt most natural to desire that the wound should be healed as quickly as possible; and probably, in these cases, it was best to try to obtain a union by the first intention. But in secondary amputations, and in those performed for diseases of the limbs, when the incisions were made through diseased tissues, there was no use whatever, but, he believed, a disadvantage, in bringing them together. They would almost invariably open again, and place themselves in the position in which they had better have been left from the first. This was especially the case when limbs were amputated for diseases which had been connected with a considerable discharge. In all these it was dangerous to stop the discharge too suddenly, and it had been proposed to make an issue near the end of the stump, to keep up an artificial drain to replace that which had been cut off. But this method, he thought, would be very inconvenient, and such indeed as could scarcely be put in practice; another, which he had sometimes adopted, and which seemed to fulfil all the intention, consisted in passing a skein of silk through the lower part of the wound, and thus maintaining, for a time, a constant irritation and a discharge of matter, which afterwards might be gradually reduced.

Mr. Benjamin Phillips said that it was a source of great gratification to him to find that the results of the inquiries which he had made some years ago had been now, of late years, repeatedly and completely confirmed. Some years ago a paper of his had been read at this society, detailing the results which he had drawn from an analysis of all the cases of amputation that he could meet with; but the conclusions to which he had arrived were at that time so contrary to the generally received opinions in this country, that it was believed that there must have been some great error in his calculations, and the council of the society had decided that it would not be safe to publish his paper. At that time the North London Hospital was the only one in London at which any regular record of the results of operations was kept, but now he had been glad to find the system considerably extended, so that the number of cases admitting of analysis had lately very much increased, and allowed of conclusions being drawn with a degree of certainty before unattainable. Nothing was more important than that conclusions should not be drawn from a small number of cases, and, as an example, he could have nothing better than the statements contained in the paper just read. When he made his inquiries, the records of the North London Hospital showed that 23 amputations had been performed, and of that number only one case had died; whereas now, 66 amputations, it seems, have been performed, and 10 have terminated fatally. The same could be illustrated by an examination of the cases of amputation at the Boston Hospitals; the proportion of deaths among the cases occurring in successive periods of two years each being widely different, and varying as much as from four per cent. to near fifty per cent. It was plain, therefore, that certain results could be drawn only from the analysis of very large numbers of cases. In his paper he had compared 650 cases, and the result was that the mortality was $23\frac{1}{2}$ per cent., and that result was deemed so extraordinary and improbable that every one thought there must be some error in it. But since that time several other reports had been published from Boston, Massachusetts, the Glasgow Infirmary, and the Liverpool Infirmary, and these had enabled him to make up his list to 1150 cases, and the result of all these was, that the average mortality was 27 per cent. He did not regard it as a matter of so much importance as some seemed to think it, to determine what was the amount of mortality in this or any other operation; it could not much influence the question of whether in any given case the operation should be performed or not; yet, at the same time, the average chance of recovery ought in all cases to be taken into consi-

deration in recommending any operation. He thought it important that we should possess not merely a knowledge of the gross amount, but, if possible, of the circumstances which render it greater or less, and this could only be obtained by tables marking the limbs amputated, the modes of operation, the disease or injury for which it was performed, the age and other circumstances of the patient; for on all these the greatest differences of result depended: if twenty arms were amputated, it was probable that there would not be more than one fatal case, but the deaths would probably be much greater in twenty amputations of the thigh. And so again in any hospital where the greater number of amputations were performed for diseases of the joints, as at St. George's, the results would always appear much more unfavourable than where the same operations were performed for accidents. And again in the case of accidents, the results obtained by a surgeon, who always did his best to save a limb from being amputated at all, would constantly seem less favourable than those obtained by one who usually amputated at once. All these things required much further investigation; nor would it be possible to make them out except by the accumulation of a considerable number of cases bearing upon each.

UTERINE HÆMORRHAGE.

To the Editor of the Medical Gazette.

SIR,

IF you judge the following case of uterine flooding worthy of a column in your valuable periodical, it is at your service.—I am, sir,

Your obedient servant,
A STUDENT OF OBSTETRICY.

Guy's Hospital, May 4, 1841.

C. D., a stout Irish woman, æt. 35, living in White Street, Borough, requested my attendance at eleven o'clock on the morning of Friday, March 19th, she being then in labour with her sixth child. Uterine pains had commenced five hours previously, and had continued constantly and severely until half-past ten o'clock, at which time the membranes ruptured, and she sent for me. Immediately on reaching her residence, I proceeded to make an examination, and found the child's head presenting naturally, and distending the external parts: in a few minutes it was expelled.

Uterine action was now for a short time suspended, but when resumed, one strong pain forcibly expelled the child, and with it a large quantity of dark-coloured blood. I grasped the lower parietes of the abdomen

with my hand, and felt the uterus gradually getting smaller and harder, although a considerable flooding still continued. In a short time the uterus became firmly contracted, and the hæmorrhage very trivial. I then tied the umbilical cord; the child was full grown, and healthy. After remaining in the house nearly an hour, during which time but a very little blood was lost, I proceeded to withdraw the placenta. But the slightest attempt to accomplish this by traction of the umbilical cord was followed by its rupture, and thus for five or six times, whilst using the utmost care, the funis snapped—at last close to its placental insertion. I then introduced my fingers into the vagina, to withdraw the placenta, but this, in like manner, broke down beneath the pressure of the fingers; and it was not until the entire mass had been grasped, that its withdrawal could be effected: it was much discoloured, and of offensive smell: the membranes came away with it. A large gush of fluid, and partly coagulated blood, immediately followed the removal of the placenta. The uterus was still apparently firmly contracted, notwithstanding which, however, I applied cloths dipped in cold water to the lower part of the abdomen and vulva. The woman now complained of feeling faint, but as the pulse was still, comparatively speaking, strong, and no alarming symptoms, excepting the hæmorrhage, were present, I did not attempt to arrest the approaching syncope. She continued in a state of faintness for some time, during which the bleeding was almost entirely stopped, a small discharge only occasionally taking place: the *uterus remained contracted*. Knowing that the flooding must depend on an extraordinary disturbance of the circulation, I had the doors and windows opened, and allowed my patient to be but very lightly clothed. She recovered from her state of syncope slowly, and the bleeding did not return. I remained with her half an hour, and then (my residence being but a few minutes' walk distant) left her, having tightened a bandage previously applied, and forbidden any conversation to be held with her, or remarks which might excite her to be made in her presence.

In about an hour I was hastily summoned, the messenger informing me that she had begun to "bleed worse than ever, and that the bed was soaking through and through." I made as much haste as possible to the house, taking with me a small bottle containing tincture of digitalis, which I had obtained, fearing that the hæmorrhage might return.

On reaching the patient's room, I found that, in consequence of her having complained of chilliness, her friends had kindled an immense fire, which made the small room

insufferably hot, closed the windows, and heaped all the clothes of which they could possess themselves upon her person. I had the fire immediately diminished, and removed all the clothes, excepting a sheet. The woman had been some time in a state of syncope; the countenance and lips were bleached, the breathing hurried, the pulse was very feeble, the extremities cold. On placing my hand over the abdomen, I found the uterus quite as perfectly contracted as when I had left, an hour before, or as it is usually found after labour. Any person not being aware of the circumstances, on feeling the state of the uterus through the abdominal parietes, would have pronounced the woman, for the time at least, perfectly secure from flooding. In a short time the pulse became stronger and more frequent, and consciousness returned; a small discharge of blood also threatened a return of the hæmorrhage. I then gave twenty drops of the tincture of digitalis, and in a short time its beneficial effects were remarkable; the pulse became softer, and its rapidity diminished. I watched the case until the evening, and repeated the tincture of digitalis twice. The flooding never returned with alarming violence after the administration of the first dose.

I have troubled you with the above communication, because I consider the case very remarkable. I am aware that disturbance of the circulation, violent action of the blood-vessels, does occasionally excite uterine hæmorrhage, even when the uterus is *disposed* to contract; but in this case the contraction was perfect. I am fully satisfied that there was no *sudden relaxation* of the uterine parietes, which, by opening the mouths of the vessels, permitted the flooding to take place, because for nearly three quarters of an hour I was firmly grasping the abdomen, and feeling the hard contracted uterus within my hands. I must not omit to state that before I was sent for to the case at all, the woman had been well plied with spirits "to comfort her," and this of course would excite and disturb the circulation: her previous labours, however, had been all attended with flooding, in a degree more or less alarming. The quantity of blood lost was amazing: I will not venture to say how much. Is it possible, considering the carious state of the placenta and funis, that the uterine vessels might be in the same way weak or diseased? But supposing this to have been the case, does it in any way explain this strange occurrence?

CASES

OF

DISLOCATIONS AND FRACTURES
IN THE CERVICAL PART OF THE
VERTEBRAL COLUMN.

BY DR. SCHUK, of Vienna.

CASE II.—*Dislocation without fracture.*—

Far more rare than the dislocations of one oblique process are the cases in which both articulating processes are luxated, so that one remains fixed on the point of the corresponding process of the vertebra next below it; while the other, having been raised up to the top of the corresponding process of the next inferior vertebra, has passed over it and to its anterior surface. This cannot take place without disruption of the bodies of the vertebrae, tearing of the intervertebral cartilage, narrowing of the vertebral canal, and violent crushing of the spinal marrow. In such cases the part of the column above the situation of the dislocation suffers a slight twisting on its axis, and does not lie in a line with that which is below; there are thus two axis lines, of which the upper is somewhat the nearer to the middle line of the body, and forms a very obtuse angle with the lower. The direction and position of the spinous processes of the vertebrae above the luxation are correspondingly altered; but, in the living subject, this can be discerned only in very lean persons. The symptoms during life are, therefore, pain, impeded motion of the neck, turning of the head to one side, and all those of crushing of the cord. The same symptoms would undoubtedly arise from a fracture of the vertebrae, with displacement of the portions of bone. When only one articulating process is dislocated, and is raised to the point of that below it, there is no encroachment on the vertebral canal, and therefore no crushing of the cord; but the pressure dependent on the slight curve of the canal, or an effusion of blood on the spinal marrow, as well as the concussion which the latter receives simultaneously with the luxation, may produce similar disturbances in the nervous system; in practice, therefore, the diagnosis of one kind of luxation from another, or from fracture with displacement of the portions of bone, is sometimes quite impossible.

F. F., a robust man, thirty-three years old, fell down in his sleep from a beam several feet high, and lay a long time unconscious. When he became sensible he complained of severe pain in the neck, and difficulty of moving the upper extremities. On the same day when he was brought to the hospital the following symptoms were noticed:—Intellect and the external senses

undisturbed; pain in the nape and back of the neck increased by pressure; head twisted and somewhat turned to the left, but not so firmly fixed in this position but that it could be slightly moved backwards and forwards; pain extending from the neck in the direction of the nerves to the axilla; incomplete paralysis of the extensors of the fingers of the left hand, with full power of moving the hand and elbow-joint; motions of the lower limbs free; urine and faeces healthy, and passed naturally; pulse slow. The spinous processes could not be traced through the deep layer of fat by which they were covered. Attempts at reduction were made; the first was of no avail, but the second succeeded in setting the head straight, and rendering it tolerably capable of motion in all directions; but the back of the neck still remained sensitive on pressure. Cold lotions, and the abstraction of a pound of blood, were ordered.

Next day the patient had retention of urine, and, in the evening, creeping pain and loss of motion in the left arm, as well as in the left foot, but no destruction of sensibility; his pulse beat only about thirty times in the minute. He was again bled to a pound.

On the second day after the accident, he had difficulty of swallowing; his respiration was effected only by the diaphragm and abdominal muscles, and he made constant efforts to expectorate hard and tough mucus; the pain in the arm was diminished, but it was frequently twitching about. The pulse was 42; leeches were applied to the back of the neck.

On the third day he had paralysis of motion, but not of sensation, in all the limbs, and had still no power of passing his urine. His intellect was undisturbed; his pulse varied, and, notwithstanding his difficulty of breathing and of expectoration, he was in good spirits.

On the night of the fourth day he had a severe rigor, followed by heat; he was restless and slightly delirious, and had frequent twitchings in all his limbs; he could turn his head round with ease, but could not so easily move it backwards and forwards. The neck was again leeches.

In the two following nights he had the same symptoms; on that of the seventh day he was again restless and slightly delirious, and his sensibility was diminished both on the extremities and on the trunk; he lay motionless on his bed like one dead, or like a living head set on a lifeless trunk. The temperature was equal over the whole body, and not increased; but the patient complained of an excessive internal heat, so that he could not bear to be covered by more than a single sheet. His respiration continued the same; and thus, with little change, he went on till the twelfth day after the reception of the injury, his respiration

growing gradually worse, till, with a sudden aggravation of its difficulty, he died.

At the examination of the body there was found, as soon as the vertebral column was exposed, a separation between the fifth and sixth vertebræ, so that the whole of the column above the latter projected for half an inch forwards. The right articulating process of the fifth vertebra had mounted over the corresponding process of the sixth, and was now in connection with the anterior surface of the latter; while the tips of the left articulating processes of the same vertebræ were impacted one upon the other. By extension the dislocated parts could be replaced; and again, by pressure and sliding them upon one another, they could be returned to the same abnormal position, and no other; they could, therefore, have had none but this position during life. The intervertebral cartilage was torn and crushed, and the spinal marrow, from the fourth to the sixth vertebræ, squeezed flat, very soft, and reddened by effused blood, with its grey substance nearly fluid, and its dura mater injected. The lungs were œdematous.

CASE III.—*Dislocation without corresponding fracture.*—J. P., æt. thirty-five, fell from a cart, first with his neck upon the shaft, and then with his head upon the ground. He felt severe pain in his neck, and became immediately paralytic in his hands and feet. He was bled, and two days afterwards was brought to the hospital, quite conscious, speaking plainly, though slowly, with his respiration weak and slow, his deglutition easy, his pulse weaker and slower than natural, his abdomen slightly distended, retention of urine, which when drawn off was normal in its characters, costiveness, and a decreased temperature of the skin's surface. From the middle of the back up to the head, and especially at the lower part of the cervical region, the vertebral column was excessively tender; the pain was increased by moving the head backwards, but not materially affected by the rotatory motions. The upper and lower limbs were completely paralyzed as to their power of motion, and the arms, from below the insertion of the deltoid muscles, and the whole of the body below the mammæ, were completely insensible.

On the next day, his speech was slower and more indistinct; the respiration and circulation still more feeble and slow; the abdomen more distended; the heat still further diminished. In the evening he had delirium, and his pulse could not be felt; towards midnight his consciousness again became clear, and at 3 A.M. he died.

On examination, the fifth cervical vertebra, with all those above it, was found projecting three or four lines before the sixth,

and the inferior articulating processes of the fifth were placed in front of the superior articulating processes of the sixth. The anterior vertebral ligament, and the ligamentum subflavum, as well as the intervertebral cartilage between the two, were torn; the spinal marrow was squeezed flat, and was crushed soft, and there was some blood around the dura mater. There was also a vertical fracture between the bodies of the fourth and fifth vertebræ, but there was no mobility of the fractured portions, for a small portion of bone at their anterior surfaces remained and held them together.—*Medicin. Jahrb. des k. k. Österreichisch. Staates*, Bd. xxi. St. iv.

HARROWGATE WATER.

THE water [of the Montpellier sulphur spring] is perfectly colourless and transparent, and almost brisk from the escape of gas. The first impression on the tongue is intensely salt, followed by the peculiar bitter taste of salt water, but leaving an *après-goût* like that which remains after chewing bitter almonds. It goes down oily, and at the temperature at which I drank it (115°) the sulphuretted gas is scarcely perceptible. I repeated the same quantity four times, diminishing each time the artificial temperature, until I drank it cold, thermometer then marking 52°, while the external atmosphere was at 60°, and the nauseous taste had increased with the descending temperature.

The whole quantity I took in four times, I noticed people to drink at twice only, and quite cold. Writers on this water have recommended the latter practice. This is an error which I was sorry to see committed at all the English Spas. There are few stomachs which can bear with impunity the weight of two doses of three-quarters of a pint each of a cold, salt, and sulphuretted water, drunk with a short interval between. Few stomachs can stand the slow extrication of the imprisoned gas, which, once ingested with the cold water, is gradually disengaged by the warmth of that organ. It then mounts into the head, and produces a confused, heavy, and unpleasant feeling.

This I have put to the test of my own personal experience. Drunk quite cold, I found the water particularly heavy on the stomach, and in an hour's time my head ached not a little. Some of my younger patients in this place experienced similar effects; and, indeed, upon inquiries among strangers, who were religiously following the recommended practice, I ascertained the case to be precisely the same. At all events the first glass or two should be warmed, but not so much so as to drive off the whole of the sulphur gas. With respect to quantity, that point has been determined by long

experience, and by very competent authorities. It did not appear to me that people on whom devolved the management of the water, at the several Spas I visited in this country, were sufficiently aware of the importance of this consideration. The quantity drunk, at one time, should be such that, during the fifteen minutes' walk which is to elapse between one dose and the next, the stomach may have got rid of the first before it receives the second. Four ounces of liquid ingested will nearly disappear from the stomach in the course of twenty minutes, particularly when assisted by walking exercise.

Such is the opinion and practice at the Spas in Germany, where beakers holding hardly as much as four ounces are used by every individual, and not the half-pint and *whole-pint* tumblers which we see employed here, at Cheltenham, Leamington, and elsewhere.—*The Spas of England, by Dr. Granville.*

BY DR. WATSON.

LECTURE XXXVI.

Epilepsy, continued. Recapitulation. Exciting causes. Simulated epilepsy. Diagnosis. Prognosis. Treatment; during the fit; during the intervals; during the warnings.

ON Tuesday last I began to speak of epilepsy: but as some of the gentlemen belonging to the class were prevented by the weather, or by other circumstances, from being present at our first re-assembling after the holidays, I will very rapidly retrace the substance of the last lecture.

An epileptic seizure may be very severe; or very slight. The very severe attacks are characterized by a sudden cry, an immediate loss of consciousness, general and violent convulsions, and subsequent coma or heavy sleep. The very slight attacks consist in a momentary abeyance of the mental faculties, sometimes with and sometimes without slight and partial convulsion. These extreme forms of epilepsy we judge to differ only in degree, inasmuch as they both attack the same persons at different times; or the one form conducts to the other. Between these the gradations are innumerable. We call the extremes the *epileptic fit*, and the *epileptic vertigo*; the French call them the *grand mal* and the *petit mal*.

These fits may last from a few seconds to half an hour. Paroxysms apparently longer than this commonly consist of a succession of fits. The average duration is from five to ten minutes.

The fits recur at variable intervals; which are sometimes periodic, mostly irregular. There may be many in a single day; there may be only one for many years. They are commonly more severe in proportion as they are less frequent.

The epileptic seizures sometimes begin in early infancy: another period at which they often commence is about the age of seven or eight: another about fourteen or sixteen, or for some few years after that age. They more often begin before puberty than after it. Sometimes the first fit takes place in the middle period of life; sometimes even in declining age. They often occur in the night, especially in the outset and the decline of the disease; usually when the patient is between asleep and awake; *i. e.* at the commencement or the termination of his slumber.

In the majority, perhaps, of cases, the fit is unexpected, and preceded by no warning. But in other instances there is some alteration perceptible by the patient himself, or by his friends, giving notice of its approach; some change in the temper, feelings, appearance; some disturbance of the senses; ocular spectra; or what is called the epileptic aura, a creeping sensation arising in some part of the surface, generally of the extremities, and gliding towards the head. Some of these warnings precede the paroxysm by a day or two, or a few hours; some by two or three seconds only. Sometimes the blow is threatened by their appearance, but it does not fall.

The fit is almost always, in its severer forms, attended and followed by coma; sometimes after the coma by temporary confusion of mind: deafness; slight paralysis; delirium; inarticulate speech. There is seldom any marked permanent alteration effected by a single fit.

A repetition of the fits leads, in a large majority of instances, first, to a defect of the memory, and of the general intelligence;

and at length to a peculiar expression of countenance, to decided imbecility of mind, to complete fatuity; and with this there is often associated some paralysis or muscular debility.

The convulsions take place, necessarily, through the medium of the spinal cord and nerves—just as voluntary movements do; but the suspension of sensation, thought, and volition (which suspension is seldom absent, while the irregular muscular action often is awaiting) shews that the *brain* is essentially involved in the disease.

Accidental organic lesions are sometimes (and sometimes only) found in the encephalon, or in the spinal cord, of persons who have suffered epilepsy uncomplicated with any permanent mental or paralytic affection; tubercles, for example, or bony growths from the interior of the skull; but as these are *constant*, and the paroxysms are *occasional*, and as in the intervals they give no signal of their presence, we can only regard them as being probably predisposing causes of the seizures.

When the epilepsy *has* been complicated with permanent alienation of mind, or some degree of paralysis, evidence of chronic inflammation of the brain and its membranes is generally discovered. This has been the consequence of the repetition of the paroxysms. This explains the frequent connexion of fatuity and palsy with epilepsy of long standing.

The diseased condition which excites the paroxysms may be situated in the nervous centres themselves, or in some other part of the body. In the one case we call the disorder centric, or idiopathic; in the other, eccentric, or sympathetic. We cannot always be sure with which species of the disease, the centric or eccentric, we have to deal: but the distinction, when it can be made, is of considerable importance, in respect to the prognosis, and in respect to the management of the case.

The predisposition to this fearful complaint is often hereditary: malformation, or defect of symmetry in the two sides of the head, is a frequent predisposing cause; so, pre-eminently, is the scrofulous diathesis: and these two, viz. the scrofulous diathesis, and a peculiar conformation of the head, are both liable and likely to be propagated from parents to children. But the predisposition is found to be hereditary even when the shape and structure of the body is, to all appearance, quite perfect and natural; and when no outward indication of the strumous diathesis is perceptible.

At the very close of the lecture I informed you that it is an unsettled question—and it is not a question of very great importance—whether the disease is more common in

females or in males: whether the *sex* has any thing to do with the predisposition.

There are certain vices, which are justly considered as influential in aggravating, and even in creating, a disposition to epilepsy: debauchery of all kinds; the habitual indulgence in intoxicating liquors; and, above all, the most powerful predisposing cause of any, not congenital, is masturbation—a vice which it is painful and difficult even to allude to in this manner, and still more difficult to make the subject of enquiry with a patient. But there is too much reason to be certain that *many* cases of epilepsy owe their origin to this wretched and degrading habit: and more than one or two patients have voluntarily confessed to me their conviction that they had thus brought upon themselves the epileptic paroxysms for which they sought relief.

Exciting causes.—Among the *exciting* causes of epilepsy, fright is conspicuous. And any *strong mental emotion* is apt to produce the fit, in a person who is already subject to the disease. This fact alone would be enough, I conceive, to forbid our ascribing the paroxysms exclusively to an affection of the spinal cord. Bodily pain; manifest and great disturbance of almost any of the principal functions of the body; may act also as exciting causes. Sometimes the cause is obvious, sometimes it is quite inscrutable. If the attack occurs every night, Dr. Bright thinks it may be attributed to the “congestion” of sleep: if it takes place at monthly intervals in women, we may “often trace it to nervous irritation in sympathy with the uterus; and when long periods have intervened we may usually trace each distant paroxysm to the repetition of some excess, or to a neglected state of the bowels.” In these latter cases, the epilepsy is of the sympathetic, or eccentric kind; the irritation being seated in some part at a distance from the nervous masses, in the stomach, or intestines, or uterus. Now I would suggest the expediency of observing what muscles or sets of muscles are *first affected* by the spasm in such cases, and in what part the warning aura (if there be any) arises: because by accurately noting these particulars, we may be led to a knowledge of the part or organ in which the irritation operates: and if we know the *seat* of the irritation, we shall be more likely to know its *nature*, and its *cure*.

Among the exciting causes of epileptic fits are also enumerated—and I believe, from what I have myself noticed, with great justice—the repulsion of eruptions, and especially of eruptions about the head, when proper artificial evacuations are not employed at the same time; the cessation of habitual discharges; and, on the other hand, profuse

and unusual discharges. Hæmorrhage certainly will often bring on convulsions and a state of insensibility exactly like certain forms of epilepsy. Persons who are bled till they actually faint, are often at the same time convulsed. And animals that are killed by loss of blood, are always affected with convulsions before they expire.

There is yet another very singular occasional cause of epilepsy that deserves to be mentioned; viz. the sight of a person in a fit of that disease. This has been noticed over and over again. Not only will a patient who has already suffered such attacks often fall into one upon seeing another so affected; but people will even sometimes do so who have never before shewn any symptom of epilepsy. In this way the disease will now and then run through a boarding-school; or through a ward in a hospital. There is a very good example of this recorded in the 11th volume of the *MEDICAL GAZETTE*, by Dr. Hardy, of Bath. A strong healthy young man was hired to take care of an older patient, who suffered frequent and exceedingly violent paroxysms of epilepsy. He remained with the patient night and day; and at the end of seven weeks became himself epileptic in a very high degree. An acquaintance of his, of equally robust make, but some years older, occasionally visited the parties. In a fortnight from his first visit he also was seized with similarly violent attacks. Dr. Hardy quotes the following short case also from Baglivi:—"Vidimus, anno 1690, in Dalmatiâ juvenem gravissimis correptam convulsionibus, propterea quod inspexerat solummodo alium juvenem dum epilepsiâ humi contorquebatur."

Dr. Cullen, who, as well as many others, had noticed the same thing, starts the question whether this mode of propagation of the disease be imputable to dread and horror; or to the mere force of imitation, which is often so strong, in health as well as in disease: and he decides in favour of the force of imitation: and in fact there are many other sights equally horrifying with that of a person in convulsions; yet there is *no spectacle* of horror so efficacious in producing a fit of epilepsy in others, as that of a person suffering under epilepsy.

This principle of imitation holds good in many of the spasmodic diseases; and in some of them, especially in hysteria, its influence is more remarkably seen than in epilepsy; and I shall therefore have to recur to it again. There is one very curious fact, however, which relates to epilepsy in particular. You are aware that this disease is often feigned, by impostors. Now I believe it is ascertained beyond the possibility of doubt that fits and actions which were at first, in these pretenders, strictly voluntary,

have at length become involuntary and uncontrollable, and have passed into paroxysms of real epilepsy. The rogue is caught in his own trap.

And the mention of these impostors leads me to consider the *diagnosis* of epilepsy. First, how are we to distinguish the feigned disease from the true? Secondly, are there any other real diseases which may be mistaken for epilepsy, or for which epilepsy may be mistaken?

Simulated epilepsy.—In the number of *feigned* diseases epilepsy is one of the most common. Soldiers and sailors pretend to have epileptic fits, in the hope of obtaining their discharge from the service. Cases of simulated epilepsy occur also continually in our streets among mendicants, and impostors who think to excite the compassion and pecuniary charity of the credulous; and are even sometimes actuated I believe by a desire to obtain admission into hospitals, where they live tolerably well, and quite idly. It is easy enough, they think, to throw their legs and arms about, and to grin; and many of them get up a capital shew of foaming at the mouth, by placing a bit of soap between the gums and cheek. The means of detecting these vagabonds are of some importance to us all; and it is more particularly necessary that they should be well known to those who are likely to join the medical department of our fleets or armies.

It is of course desirable, in questionable cases, to witness a fit. But pretenders are not very willing to perform when they know that a medical man is looking on. You may sometimes convict them, in the absence of the fits, by cross-examination. A cheat will seldom be consistent in the account which he gives of his fits; as to whether they are regular or irregular; and as to the times and places in which he has suffered them. An impostor chooses such situations for his exhibition as are most suitable to his own purposes; a crowded street, or a well-frequented public walk. True epileptics almost always select retired places to take exercise in; especially if they have any warning or expectation of the approach of a paroxysm. You will find also that the impostor is not attacked at his own home; but always fixes upon some spot in which he is not only sure to be seen by others, but in which he is not likely to sustain any injury by tumbling down. True epileptics often get themselves seriously hurt by their falls; feigned ones generally come off without much bodily damage. However, if the fits are alleged to be frequent, and if also they are regular, you may soon expect one, and must make a point of being present; and then you will seldom fail to remove or to verify your suspicions. In the first place the muscular power of epileptics is far beyond what is

natural. It will sometimes take four or five stout men to hold a weak emaciated lad, in a fit of epilepsy. Of course no impostor can command more than his natural strength. In the second place a real epileptic fit, if it lasts long, is seldom violent; whereas impostors, for obvious reasons, make their fits both long and violent. You may often get much information from the state of the eyes, which in true epilepsy are generally partly open, with the eye-ball visibly rolling and distorted. In feigned epilepsy the actor almost always prefers to shut his eyes completely. Sometimes, if he be closely watched, and no suspicion is expressed, he will be seen to open his eyes occasionally, to ascertain the effect of his exhibition upon the bystanders. In real epilepsy, too, the pupils are often considerably dilated, and do not contract when stimulated by light. This is a very sure criterion: for no impostor can prevent his iris from acting on exposure to vivid light. The pulse, in true epilepsy, is not only frequent but often irregular also; a circumstance which never can be imitated. The skin of an epileptic, during the fit, is commonly cold: but that of an exhibitor is hot, and covered with sweat, obviously the consequence of his violent and voluntary exertions. In this respect, also, it is scarcely possible for him to deceive us. Again, an impostor will not bite his tongue, as epileptics often do; nor very willingly void (like them) his excrements and urine during the fit: indeed it would not be very easy for him to do so, and at the same time to carry on the necessary pretence of convulsions. Besides, epileptics, during a fit, are quite insensible to external impressions; and hence the vulgar modes of detection, though harsh and not to be recommended, are often effectual ones: such as dropping melted sealing-wax upon the patient; putting some gin in his eye; burning him with a hot poker; or (what I believe is more fashionable among headles and police constables, when they have to administer to such patients) the pressing your thumb-nail violently under that of the supposed impostor. This causes exquisite pain, yet inflicts no lasting or serious injury; and I believe that few pretenders stand out against this expedient. It is astonishing, however, how much torture some of them will bear before they can be brought to confess their imposition. If we speak of having recourse to some of these painful tests in the hearing of the pretender, we shall find that the fit will soon come to an end. Dr. Cheyne mentions an instance in which one table was placed upon another, and a soldier, who was supposed to be shamming, was laid upon the upper one, while his paroxysm was on him; and the fear of falling from such a height soon stopped the convulsions. Mr. Hutchinson relates the

case of a sailor who was suspected to be a cheat, in whom the convulsions were instantly removed by blowing some fine Scotch snuff up his nostrils through a quill. This brought on *another* kind of fit, viz. a fit of *sneezing*, which lasted nearly half an hour; and there was no return of the epilepsy as long as Mr. Hutchinson remained in that ship. He tried the same expedient in cases of *real* epilepsy, but never could produce any similar effects, although the patients were not snuff-takers. There was a beggar in Paris, who often fell into epileptic fits in the streets: one day some compassionate spectators, fearing that he might injure himself in his struggles, got a truss of straw and placed him upon it; but when he was in the height of his paroxysm, and performing remarkably well, they set fire to the straw; and he presently took to his heels.

There is another ingenious plan, very likely, I should think, to detect an impostor, and yet not calculated, like the one last mentioned, to injure a real sufferer; which is, to propose gravely, in his hearing, to pour *boiling* water upon his legs, and then to proceed actually to pour *cold* water upon them.

Diagnosis.—Of the *real* diseases which are apt to be confounded with epilepsy, *hysteria* is the chief. The question whether a given case be one of epilepsy or of hysteria, very often arises. By a careful attention to several circumstances, the discrimination is generally to be made. In the first place the total suspension of consciousness, which is so constant an accompaniment of the epileptic paroxysm, does not take place in the hysterical: in epilepsy there is no globus hystericus, no alternations of laughter and tears: the solitary cry which ushers in the epileptic attack so frequently, and which is so characteristic, is not heard in hysteria; not that hysterical girls do not scream, for they often do; but then it is repeatedly and continuously. The heavy comatose sleep that succeeds epilepsy is not common in hysteria. Hysterical patients contrive also to avoid hurting themselves by their contortions: they do not bite their tongues, nor foam at the mouth. Dr. M. Hall tells us that, in epilepsy, there is a forcible closure of the larynx, and expiratory efforts which suffuse the countenance, and probably congest the brain, with venous blood. In hysteria the respiration, on the contrary, is rapid and sobbing.

Observe that I have been speaking, all along, of what has been sometimes called *habitual* epilepsy. It is not every attack of convulsions with insensibility which ought to be so named. Such attacks are apt to follow sudden injuries done to the brain; stunning blows on the head, fractures of the skull, the eruption of blood in sanguineous apoplexy, and even

overwhelming emotions of the mind. With these casual occurrences of epileptiform convulsion I do not here meddle.

Prognosis.—Epilepsy is one of those complaints concerning the *probable issue* of which the patient, and still more the patient's friends, are sure to make repeated and anxious enquiries. It is seldom that we can pronounce with any confidence a favourable prognosis; but there are some cases in which the prospect is much worse than in others.

If we have any reason to believe that the disease is *centric*, and connected with any organic derangement of the nervous centres themselves, the prognosis must be bad. *Ceteris paribus* it is rendered worse by the coexistence of any sign of scrofulous disease, or of the well-known bodily characteristics of the scrofulous diathesis: it is rendered worse, also, when the disease has occurred in the parents, or among the more immediate ancestors, of the patient; whenever, in short, there is reason to think the disposition to it is inherited. The prognosis is bad when the complaint occurs in persons who have slanting foreheads and misshapen skulls; and when the epileptic physiognomy has become established. The prognosis is always the more unfavourable the longer the disorder has lasted; the oftener the fits have been repeated; and the more habitual they have become. And when the memory is permanently enfeebled, or fatuity has come on, or the disease is complicated with any form or degree of paralysis, the case is hopeless; so far, at least, as a perfect cure is concerned.

On the other hand the prognosis is better when the disease is *eccentric*; i. e. when there is any obvious exciting cause of the paroxysms, manifest in structural or functional disorder of some part of the body other than the nervous matter. And when this eccentric cause is removable—a stone in the bladder for instance, worms in the intestines—then the prognosis still farther improves. On this account the prognosis is better in children than in older persons, for the exciting cause is often clearly eccentric, and likely to be transitory; the irritation of teething for example: and besides this, it is stated by many practical writers that even repeated and habitual attacks of epilepsy in children often go off as the patients grow older; and especially at the age of puberty. The experience of Heberden, however, was against this. He says that he had known several persons become epileptic at that time; but that he had never met with one who had then got rid of the disease. He had known a few who had recovered before, and some after the age of puberty. Dr. Elliotson mentions a case in which a girl had epilepsy prior to the first period of menstruation: then the fits stopped; and she remained free

from them until in advanced life the catamenia ceased to recur: and then the epilepsy returned. In all those cases in which we can assign some evident cause for the fit—such as the use of improper food, uterine irritation, mental emotion, and so on—the prognosis is somewhat better than usual. “The eccentric epilepsy (says Dr. Hall) is to be viewed as *curable*, however *difficult* of cure.” And however unfavourable the prognosis may be, there is nothing that can excuse any apathy or neglect of it on the part of the practitioner. Though few cases of habitual epilepsy admit of a *cure* under any treatment, yet there are few which may not be *relieved* by treatment, so far as regards the *frequency* or the *violence* of the fits, or *both*.

Treatment.—The treatment of epilepsy resolves itself into the measures to be adopted during the fit; and the measures to be adopted during the intervals between the fits.

During the fit.—In the paroxysm itself we have to provide against the risk of injury from the struggles and contortions of the patient; and if possible to mitigate the violence, and to shorten the duration of the fit. The patient should be placed in the centre of a large bed; his neck-cloth, and any ligatures about his person, should be loosened: his head should be somewhat elevated. When the risk of his hurting himself cannot be avoided in any other way, his limbs should be restrained by the bystanders, or secured in a waistcoat. Some persons have advised that a piece of cork or soft wood should be placed between his teeth, to prevent him from biting his tongue, or breaking his teeth. But it is not easy to manage this expedient cleverly. If the head be visibly congested, and hot, cold wet cloths may be applied to it with propriety; and if, at the same time, the extremities be cold, means of restoring warmth to them should be adopted.

I do not know whether art can abbreviate the paroxysm. Some years ago the late Barry O'Meara wrote a letter to some of the newspapers, saying that he fancied he had seen a popular remedy useful in such cases; that, namely, of cramming salt into the patient's mouth: he thought he had succeeded in bringing the patient about by that expedient. Of the epileptic patients that come into hospitals, the physician, not being always on the spot, does not see all, or even many of the paroxysms; but after reading that letter, I desired the nurses to treat all my patients who might be seized with epilepsy in the wards upon that plan: and upon comparing the length of the paroxysms when the salt was used, with their ordinary duration as reported by the friends of the patient, or as previously observed in the hospital during some of the earlier fits, it certainly

did seem to curtail the convulsions. Probably it is more calculated to relieve an hysterical than an epileptic fit. In the epileptic fits of children much benefit often results from immersing them in warm water: particularly if there be any coldness of the extremities.

It is very much the fashion to bleed persons who are seen in a fit, of whatever kind; and to bleed them largely. I have already given you my opinion of the indiscriminate use of this decided measure in apoplectic attacks. If it be clear, from the phenomena, or from the known history of the patient, that the case is one of epilepsy, bleeding, *during the fit*, will seldom be necessary or proper; unless, indeed, the evidence of cerebral plethora is very strongly marked: and even then I would advise you not to do more than take a moderate quantity of blood, by cupping, from the neck or temples. The convulsions and the sopor may be expected soon to pass off; as soon, probably, and as completely, without as with any abstraction of blood. Whereas the difference of the alternative is not trifling, in respect to the condition in which the patient will be left when the fit is over. The injurious effect of excessive blood-letting upon the system at large, is manifest, sometimes, for months afterwards.

During the intervals between the attacks we seek to prevent their recurrence; and this end is to be attained, when it is attainable at all, by getting rid of the predisposition to the disease, on the one hand, and by protecting the patient against its exciting causes on the other. Now there are certain kinds and causes of predisposition which we *cannot* get rid of: such are the tendency that is *inherited*; the strumous diathesis; malformation of the head; the presence of some organic lesion in the brain or spinal cord. Vicious and dissolute habits are also difficult, but not impossible, to eradicate. It will be our duty, when such are discovered, to set strongly before the unhappy patient the dreadful end to which he is hastening; the certain loss of reason to which, when once the disease has shewn itself, the continuance of his baleful indulgences will drive him; and to urge upon him the necessity for a short and sudden turn on his part, if he would expect any aid from medicine. Where no physical cause of the proclivity exists, or can be detected, it is of much importance to ascertain whether there be any deviation from the standard condition of health; towards general plethora in the one direction, or towards emptiness and asthenia in the other. The first of these unnatural states may be redressed by regimen and exercise, by abstinence from stimulating food and drink, and by a slender diet also; and, if need be, by

direct depletion. The second, which, perhaps, is the most common of the two, and which often leads (as I have explained before) to *local* plethora, may often be removed or lessened by a tonic treatment. The object in both cases is to give stability and firmness to the nervous system; to diminish that mobility, or readiness to be impressed, which is so strong a characteristic of the class of patients affected with epilepsy, although it may not be very apparent in some few individuals among them. It is upon this principle that *mineral* tonics sometimes do good in epilepsy, and not by any *specific* virtue which they possess in restraining the fits.

It is owing, perhaps, to a neglect of these two somewhat opposite conditions of general plethora and general debility, or to the difficulty that sometimes is met with in distinguishing these conditions, that such a variety of opinions have been expressed concerning the proper treatment of habitual epilepsy. Plethora is to be reduced without causing hurtful debility: tone is to be given without inducing dangerous fulness. It requires some nicety to carry the balance even; to attain the hoped-for good, and at the same time to avoid the evil that is apt to wait upon it. In very many cases the requisite extent and measure of the tonic plan on the one hand, or of the lowering system on the other, can only be learned by careful trials. But sometimes the indications of treatment are more plain. When the patient is young and strong, and full of blood, and not of a particularly moveable temperament; when he has a hard pulse, or any degree of feverishness; when the disorder has supervened upon the suspension of some customary discharge, so that there is an obvious cause of plethora; and when the disease is in its early stage, and the recurrence of the fits has not yet been established by habit; in any or all of these circumstances it will often be proper to abstract blood from the patient, and it will always be right to purge him actively, and to insist upon an abstinent regimen. When former paroxysms have been preceded by signs of fulness of the vessels of the head, by headache for instance, throbbing of the temporal arteries, distension of the superficial veins, a flushed or loaded countenance, you may sometimes, by a timely use of the lancet or the cupping-glass, avert an attack that was apparently impending.

On the other hand, if the patient is pale and weak; or unduly susceptible; or if his malady has been fastened upon him through many repetitions of the fit; you will generally find that any form of active depletion is injurious, and learn to place your best hope in measures which are calculated to invigorate the frame.

One of the most useful of the particular remedies employed for strengthening the body, is the cold shower bath. This tends, more perhaps than any other single measure, to give permanent firmness and stability to the system. The best test, in all cases, of the tonic and bracing effect of this remedy is the occurrence of a pleasant and general glow after each application of it. It is the only safe mode in which the cold bath can be used by an epileptic person.

You will find, in books, a great many tonic medicines recommended for this disease, which medicines you will have opportunity and ample time for trying. Of the mineral tonics, the salts of silver, zinc, copper, and iron, have been chiefly praised. The nitrate of silver used to be highly thought of; but there is one very serious objection to it which must never be forgotten: viz. that it is apt to produce a permanent discolouration of the skin, a frightful lead-colour. There is a footman in a house near Cavendish Square who has been thus blackened; and there is a gentleman of property resident at Brighton in the same predicament: his face looks as if it had been thoroughly and carefully pencilled over with plumbago. A barrister and friend of my own had a narrow escape from a similar misfortune: in fact his skin has acquired a just perceptible tinge of grey. Now if the remedy were sure to cure the disease, I am not certain that every one would accept of a cure on such terms. It would be proper, even on that supposition, to tell the patient that though he (or, *a fortiori*, she) would get rid of the epilepsy, there was a likelihood that this unamiable complexion might ensue. But the truth is that in giving this nitrate of silver we run a great risk of obtaining its disfiguring effect, for the sake of a very small chance of curing the epilepsy. I have been assured, by one of his friends, that the Brighton gentleman has carried a dark outside for a quarter of a century at least; and that he is as subject to epileptic fits now as ever he was. If the lunar caustic is to do good, it must be given for some time together, and the probability is that it will not do good even then; and if it be given for some time together, there is great danger of its changing the colour of the skin. For these reasons I never give it myself, and therefore I cannot recommend it to you. If you wish to try it, or if you have a patient that insists on trying it, as some will, you may begin with half a grain in a pill three times a day; and the dose has sometimes been carried as high as fifteen grains. And it is worth observing that in the larger doses this drug proves purgative: it is possible that its good effect, when it has any, may be attributable to its operation in that way.

There is no danger of spoiling the beauty of your patient by administering the oxide or the sulphate of zinc; or the cuprum ammoniatum. The liquor arsenicalis has been thought useful; but it requires to be exhibited with great caution. Of all the metallic remedies I should prefer some preparation of iron. I think I have seen much good done by the *vinum ferri*; not by any specific agency, however, but by its giving what is called tone to the nervous system, and rendering it less prone to be affected by the slighter exciting causes of the disease. I cannot pretend to weigh the merits of the long list of substances which have been lauded as efficacious in keeping off and curing the disease; and which, when they have been useful at all, have operated, I conclude, in diminishing the disposition to epilepsy by corroborating the nervous system. The most renowned of them are valerian, asafetida, wormwood, the misletoe of the oak, the cardamine pratensis, rue, the sedum acre, indigo; narcotic vegetable preparations, stramonium, belladonna, henlock, lettuce; animal substances, musk, castor, ox-gall; and the number might be many times multiplied: and this long array of drugs, all of which have been known, or supposed, to accomplish a cure, affords, in truth, one of the strongest evidences of the intractability of the disease under any plan of treatment. There is a shrewd remark of Esquiro's, which I believe to be quite true, however difficult it may be to account for the fact, which is, that epileptics are apt to improve for a time under every new plan of treatment.

Whatever drug you may see reason to prefer (and the patients will have drugs, and you must be prepared to ring the changes upon them), there are certain other points in the management of the disease which are of considerable importance. The patient who is subject to epilepsy should live by rule, and be temperate in all things. His diet should be simple, nutritious, but not stimulating: he should renounce all strong liquor, and become, in the new-fangled and vulgar phrase, a teatotalter. He should rise early, and take regular exercise in the open air; keeping his head cool, and his extremities warm. He should avoid all mental excitement, and the fatiguing pursuit of what is called pleasure; all probable sources of sudden anger, surprise, alarm, or deep emotion of any kind; all striving and contention of the intellect. The student, of whatever age and sort, in whom epilepsy has declared itself, should shut his books, the man of business abandon or abridge his professional toil: at least they must be instructed to abstain habitually, in their respective callings, from such application as would task and strain their powers,

whether mental or bodily; and endeavours should be made to engage their thoughts and to interest their minds in less engrossing objects of attention. No minute rules can be laid down on these points, but, keeping the general indication in view, it will seldom be difficult to follow it up in practice.

When the fits appear to have been brought on by a species of moral contagion, or by imitation of the same disease seen in others, care should be taken to exclude as much as possible those objects or trains of thought which produce the mental emotion or the morbid propensity. In these cases, and, indeed, I may say in almost all cases, it is more rational to expect benefit from such measures as tend to calm the mind and to fortify the nerves, than from this or that substance thrown at random into the stomach.

There is sometimes cause for suspecting that epileptic fits depend upon a syphilitic affection of the bones of the skull; I am much mistaken if I have not seen such cases. When that suspicion arises, it will be proper to give mercury a full and fair trial. Such a plan has been followed by success. I should always premise, however, in such cases, the iodide of potassium; the efficacy of which in getting rid of syphilitic nodes is no longer doubtful. I am accustomed to recommend a gentle and long-continued course of mercury whenever organic disease of the brain is suspected; the influence of that remedy being carefully watched. It will be right and proper also to try the effect of counter-irritation; of blisters, a seton in the neck, or the tartar emetic ointment. But I must confess to you that, often as this expedient is employed, I have seldom witnessed any such result from it as would encourage me to expect benefit from repeating it in another case. There is one form of counter-irritation which I have never seen put to the test, but which has of late been strongly recommended by a very able and observing physician, Dr. Pritchard; and which I have heard very good accounts of from a gentleman who had seen it extensively employed in Bristol; I mean the making a long issue in the head itself, dividing the integuments down to the bone by means of a scalpel in the direction of the sagittal suture, and keeping the incision open and discharging for some time, by means of issue peas. The formation of the issue is said to be not so painful as one might suppose.

Dr. Quain, in his edition of *Martinel's Pathology*, relates the following case:—"Some years ago I saw a boy who was epileptic from infancy, and who, in one of his usual fits, fell over a cliff by the sea-side, and received a very severe lacerated wound

of the scalp, which healed slowly and with a copious suppuration. While the discharge continued he was free from any epileptic attack; but as soon as the wound healed, the fits returned as before."

Twice I have seen similar good effects from the insertion of a seton in the neck. Twenty times that measure has disappointed my hopes.

When the disease is ascertained or believed to be of the eccentric kind, we must search diligently to find the seat of the distant irritation, in some disturbance of function; and apply our remedies accordingly. The irritation may be found, as I have already intimated, in almost any organ of the body. Painful or irregular dentition is perhaps one of the commonest of the eccentric sources of epilepsy. Sometimes the attacks are attended with symptoms of disease in the liver; slight yellowness of the skin, uneasiness and tenderness of the right hypochondrium, and lowness of spirits. In such a case we must rectify that state of the liver, by such means as I shall have to specify hereafter. If the disorder depends on a stone in the bladder, the cure must be committed to the surgeon. I have a patient at present under my occasional inspection, who from time to time has slight fits of epilepsy; on most occasions he passes about the same time a small calculus by the urethra. I make no doubt that in his case the exciting cause of the epilepsy lies in the kidney.

You will find that most persons, in respect to such diseases as that which we are now considering, have some favourite or usual mode of treatment; and if I were called upon to name any single drug, from which, in ordinary cases of epilepsy, I should most hope for relief, I should say it was the oil of turpentine. And I find that other persons have come to the same conclusion. Dr. Latham the elder was, I believe, the first person who made known its efficacy in this disorder. Foville states that he has seen excellent effects from it. It is highly spoken of by Dr. Percival, in the *Dublin Hospital Reports*. It is not to be given in large doses, but in smaller ones that are frequently repeated; from half a drachm to a drachm every six hours. You are aware that it sometimes produces strangury, and therefore the patient must be forewarned of this, or carefully watched. Occasionally turpentine has done good in virtue of its anthelmintic properties. I know that a physician of my acquaintance cured a case of epilepsy in this way, somewhat to his own surprise. Without having in his mind any notion of worms, he thought it might be well to purge his patient, who had laboured under epilepsy for some time, with the *oleum terebinthinæ*. The patient, who is the brother of a person

holding at present a high office in this country, was residing two or three miles out of town. In the middle of the night the Doctor was summoned to him in a great hurry; the messenger said he was supposed to be dying. He was only intoxicated, however, by the free dose of turpentine he had swallowed: the next morning he voided into the close-stool a large tape-worm; and he has never had epilepsy since. The late Lord Hardwick, the father of the present Earl, had epilepsy, and he too got rid of his epilepsy and of a worm at the same time. I believe that the cure was effected by turpentine in his case also; but I am not certain of that. Such cases are remarkably interesting: they shew that irritation of the stomach or intestines may be sufficient to cause the fits; they illustrate excellently well the eccentric form of the disease; and they deserve to be always borne in mind when we are asked to prescribe for an epileptic patient. A cure from so dreaded a complaint, by such simple means—the cause of his malady, and the certainty of his having got rid of that cause, being both so obvious and intelligible to the patient—may be enough, sometimes, to make a practitioner's fortune. But I think you will sometimes find the oil of turpentine very useful, even though it expels no worm, and when there is no worm to expel. If the bowels should be costive, the oil of turpentine and castor oil, in equal proportions, go exceedingly well together.

During the warnings.—When the patient has a distinct warning of an approaching paroxysm, can any thing be done to ward it off? Why, in some cases, by interrupting the precursory symptoms, it certainly may be prevented. A pupil of the class informs me that a brother of his, 12 or 13 years old, has been subject to epileptic fits for two years. They occur in the night, especially if he is waked, even though the awakening cause has no tendency to startle him. He often is dull and drowsy the evening before, and if he is roused from this lethargic state by conversation, or amusements, the attack expected that night sometimes does not happen. Another student knows a young girl, in whom the occurrence of very high spirits is always precursory of the paroxysm: when this extreme vivacity is moderated by those about her, the threatened fit is sometimes averted. I mentioned before an instance in which the aura, proceeding from one of the thumbs, was frequently checked by tying a ligature tightly round the thumb. Other examples of exactly the same kind are on record. Mr. Wardrop cured a case, beginning with aura in one finger, by amputating a joint of the finger. Dr. M. Hall states that the immediate accession of the paroxysm may some-

times be prevented by dashing cold water on the face, or by exciting the nostrils by snuff. In this manner the disposition to closure of the larynx and to expiratory efforts is exchanged for sudden acts of inspiration. Another patient of my own, an old College friend indeed, who is afflicted with epilepsy, feels convinced that he sometimes prevents a fit by applying smelling salts to his nose; and he always carries a bottle about with him for that purpose: but, unfortunately, the warning (which consists chiefly in giddiness) is generally so short, that he has not time to have recourse to his preventive before he falls down. It is a question whether the fit may not be obviated by a strong mental effort in some cases. I make no doubt that it may, especially in the imitative form of the disease, which originates in and depends upon mental and moral causes.

It is scarcely necessary that I should do more than advert generally to those precautions which every one who is subject to epilepsy ought to observe, and which it is the business of his medical adviser to enforce both upon the patient himself, and upon his friends. His bed should be large; or if not large it should be enclosed with some netting or other defence against his falling out of it. If he sleeps in a room by himself, care should be taken that, in the winter, a proper temperature is kept up, for if in his attacks he gets out of bed on the floor, he may be seriously injured by the cold. He should not, however, be left alone if it can be helped. Guards should be placed over every grate near which the patient may come; he should avoid ascending and descending stairs as much as he can; he should not ride on horseback, nor on the top of a coach, nor even in a gig; nor go about, especially in solitary places, without an attendant. A patient of Dr. Cheyne's, a young man of 20, was drowned in his own garden by falling into a little runnel of water which was not four inches deep. Neither, on the other hand, will it be proper or safe for him to frequent crowded or hot rooms; or the streets of a populous town, in which the multiplicity and distraction of objects are apt to produce, even in a healthy person who is not accustomed to them, a degree of vertigo and confusion. Dr. Cheyne advises that when the patient's circumstances will admit of his having a constant attendant with him, the latter should be provided with some diffusible stimulus; a potion, for example, composed of camphor mixture and æther, by swallowing which the impending paroxysm may sometimes be repelled.

ON
CERTAIN PHYSIOLOGICAL INFERENCES
WHICH MAY BE DRAWN FROM THE STUDY OF
THE NERVES OF THE EYEBALL.*

By W. P. ALISON, M.D.

Professor of the Theory of Medicine.

It has been justly observed that the great discovery of the appropriation of the different portions of the nervous system to the exercise of the different functions, would never have been clearly established, but for the fortunate circumstance that, in certain parts of the body, especially on the face, the nerves of sense and of voluntary motion are distinct throughout their whole course. And this consideration may instruct us that, when we have an organ supplied with a variety of nerves, known to be of perfectly different endowments, the study of the peculiarities of these nerves may give us an insight into the purpose or use of some of those pieces of structure in all parts of the nervous system, in which we must still admit that we see much contrivance, without understanding its intention.

In the case of the eyeball, it is generally allowed that we see, separated for us by nature, almost every kind of nerve which the physiology of any part of the body includes; we have the nerve of special sensation, and that of common sensation; we have the nerves which excite motion in obedience to the will, and those which excite motion over which the will has no control; we can point out the incident nerve and the efferent nerve, concerned in two distinct examples of the reflex function of the spinal cord; and we can specify the nerve by which the nutrition of the whole organ, and more than one secretion contained in it, are liable to be influenced and controlled. And when we attend to the peculiarities of these nerves, and to facts which have been observed in regard to their action, I think we have sufficient data for certain inferences applicable to other parts of the nervous system, which have not yet been distinctly pointed out, and which are steps in the progress of that most difficult, but likewise most interesting department of physiology, where our object is to detect the laws by which mental acts are connected with the physical changes of living beings; and where, accordingly, the intimations of our own consciousness must be admitted as part of the foundation of our inferences.

I. The first peculiarity in the nerves of the eyeball to which I wish to direct attention is this, that those supplying the muscles by which the eyeball is instinctively or volun-

tarily moved are, if not wholly, (as Scarpa and others have maintained), at least almost entirely devoid of any of those filaments which we now regard as the organs of common sensation; the straight and oblique muscles having their nerves from the 3d, 4th, and 6th, to the almost complete exclusion of the ophthalmic branch of the 5th*.

I think we cannot doubt that the reason of this peculiarity, by which the muscles of the eyeball are distinguished—perhaps from every other muscle in the body, viz. the absence of purely sensitive filaments in their composition—is that already assigned by Van Deent†, viz. that these muscles are intended to be regulated and guided in their contractions, not by sensations excited in their own substance, or in parts directly in contact with them, but by the sensations of the retina; and I think farther, that to this peculiarity we are to ascribe, both the positive fact, that the movements of these muscles are naturally *consentient* in the two eyes, so as to preserve the parallelism of the optic axes; and likewise the negative fact, that we have hardly any power to insulate an act of the will on one of these muscles, so as to move the one eyeball in a different direction from the other; i. e. the left eye, for example, turns inwards when the right eye turns outwards, because both are habitually guided by the sensations of the retina, which are similarly affected by these movements of the two eyes; and we have little power of moving either eye independently of the other, because we have hardly any sensations, consequent on the movement of the one eye and not of the other, whereby to guide the efforts of the will for this purpose‡. And this con-

* “Certum et inconvincibile ut,” says Scarpa, “quinti nervorum cerebri n. ophthalmicum, orbitam transgradientem, ne minimum quidem filamentum valde conspicuis cæteroquin nervis oculum moventibus addere.” (De Gangliis, &c. Isis, 1832.)

† De Differentia et Nexu inter Nervos vitæ animalis et vite organicæ, p. 162.

‡ It has been stated by Sir Charles Bell, that he believes the 3d nerve to be sensitive as well as motor, because it has an origin from behind as well as from before the grey matter of the crus cerebri; and although the examples of the portio dura and the spinal accessory nerves (which appear to be purely motor, although originating in part from the posterior portion of the cord) render that inference doubtful, yet I am bound to admit that, according to the statement of Valentin (a), there is experimental evidence of sensations being felt on irritation of the 3d nerve. But this author is equally confident, from experiment, that there is no sensibility in the 6th nerve (b); and it should be remembered that movements are often performed by the 3d nerve,—such as rolling the eyes inwards, and raising the eyelid,—which are not prompted by the sensations of the retinae, and for the regulation of which sensations in the moving parts themselves may therefore be required.

(a) De Functionibus Nervorum Cerebraliū, &c. p. 16.

(b) Ibid. p. 30.

* From the Transactions of the Royal Society of Edinburgh, Vol. XV. Part 1.

sideration suggests some important reflections on the *office of sensitive nerves and of sensations* in regard to all movements of voluntary muscles.

It appears to me, notwithstanding some difficulties recently raised, that the essential peculiarity of all strictly animal motion is, that it is motion dependent more or less directly on sensation; that if we are certain of any movement in an organized body being altogether independent of sensation, and affording no indication of any mental act, we should refer it to the same class as movements in vegetables; and that in designating such movements as organic, but not animal, we express a distinction of essential importance in physiology.

It has indeed been lately maintained by several eminent physiologists, who have studied the indications of what is now called the reflex function of the spinal cord, that many living actions, such as respiration, deglutition, coughing, sneezing, and vomiting, the evacuations of the bowels and bladder, and even the movements by which irritations of the surface are avoided or repelled,—certainly attended in the natural state by sensations, and usually thought to indicate sensation, and therefore to belong to the department of animal life,—are independent of sensation, and ought, therefore, according to the principle above stated, to be referred to that of organic life. But although it is well ascertained that movements may be excited in perfectly paralytic limbs, by irritations applied to the surface, which must be carried back to the sensitive, and cross from thence to the motor portions of the spinal cord connected with those limbs; and therefore that the whole series of nervous actions, which takes place when any of these reflex or sympathetic actions are excited, may be in some degree imitated by mechanical irritation of the nervous matter, independently of sensation; yet, when it is inferred from this fact that, *in the entire and healthy body*, sensation does not intervene, as a part of the sequence of cause and effect, on which such actions depend, this theory overlooks so much of what has been formerly ascertained and pointed out in regard to them, that I do not think we can expect it long to hold its ground in physiology.

The movements which are excited by irritation of the sensitive nerves, in the *undoubted* absence of sensation (which of course can only be known in the human body in the state of disease), are general and irregular, and have not the character of *selection and adaptation* to particular purposes, which is essential to the useful application of any such actions in the living body. And when it is supposed that such movements as respiration, coughing, or deglutition, are equally independent of sensation, we

not only overlook this, their essential character, of selection of individual nerves and adaptation to particular ends, but disregard the following facts, long ago stated in evidence, that sensations intervene in the process by which they are excited.

1. In various cases, impressions on the sensitive nerves of *different* parts of the body excite *the same* sensation, and then *the same* reflex or sympathetic action follows,—as when intense nausea results from changes whether in the brain, fauces, stomach, bowels, liver, or kidneys, and is in each case followed by the same act of retching,—or when a full inspiration follows the dashing of cold water on the face, breast, abdomen, or extremities.

2. Conversely, in various instances, different impressions made on *the same* parts of the body, and therefore on the same sensitive nerve, exert *different* sensations, in which case they are *not* followed by the same reflex actions. Thus certain impressions on the nostrils and face, followed by the sensation of cold or of tickling, excite the act of inspiration; but other impressions on the same parts, fully as strongly felt, but exciting different sensations, as in cutting or bruising, have no such effect; and the same is remarkably observed as to different impressions on the fauces and on the stomach, some of which excite nausea and *then* retching, while many others have no such effect. These facts plainly indicate that, in the natural state, the reflex actions, characterized as above stated, follow not the impressions on particular nerves, but the excitement of particular sensations. And it is easy to shew that many phenomena seen during sleep, or in decapitated animals, (when the medulla oblongata has been left in connexion with the cord), and which have been thought indications of even well-regulated reflex movements, independent of sensation, may be reconciled to the same doctrine, if we remember that sensations may be quite distinct, but momentary, and so leave no trace on the recollection.

Then it is to be remembered, that several of these reflex actions are absolutely identical with those which are excited by emotions and passions, *i. e.* by changes which are peculiar to the mental part of our constitution, as in the cases of sighing, weeping, laughing, even retching and vomiting; and again, that they are observed to be remarkably obedient to well-known laws of mind. Thus they are, like the strictly voluntary action, obedient to the law of habit, which, as applied to the mental changes preceding muscular contractions, is merely the law of association of ideas; and they are so effectually controlled by the occurrence of any very engrossing mental act,—sensation, emotion, or voluntary effort,—as plainly to imply, that

they are not only attended by the consciousness, but modified by the agency, of the mental part of our constitution.

I stated and illustrated these facts, chiefly by commenting on the writings of Whytt and Monro, before the offices of the brain and the cerebellum, in animal motion, had been clearly distinguished from those of the spinal cord*; and it does not appear to me that their force is in the least impaired by the facts which have been since ascertained, touching the portions of the nervous matter with which sensation, or recollection, or any other mental act, is especially connected.

The case now before us, however, is one in which we see exemplified, not merely the power of sensations, directly, or through the intervention of other mental acts resulting from them, to *excite* muscular motions, but more especially their office in *guiding and regulating* those muscular actions which are excited through the nerves. The difference between the muscles of the eyeball and other muscles of the body, in the respect above stated, illustrates perfectly the importance of the sensitive nerves of muscles, whether these are bound up with their motor nerves, as in most parts of the body, or separated from them, as in the face; and the importance of those muscular sensations, excited by the contraction of muscles, on the efficacy of which, as a means of acquiring knowledge, the late Dr. Brown dwelt with so much earnestness and ability, but perhaps with somewhat exaggerated ideas.

The office of the sensitive nerves of the voluntary muscles in general, and of the retina and the optic nerve in the eye, in regulating the animal motions, is obviously to furnish the sensations by which the mind is guided, in selecting the muscles and portions of muscles, and in determining the degree of contraction which is requisite for the attainment of any object. And of the necessity of such a regulator in the case of the eye, we have an instructive example when one eye is affected with amaurosis, the effect of which is to prevent that insensible eye from following accurately the movements of the sound eye, when turned in different directions, and thus to cause occasional and temporary distortion. In fixing on the muscles, or portions of muscles, on which it must act, when it feels certain sensations, in order to attain certain objects, the mind sometimes merely yields to that mysterious impulse, independent both of experience and of reasoning, to which we give the name of instinct; but in the greater number of cases, in our species, it is guided by experience and education. The sensations which result from any particular muscular action are recollected; and it is the anticipation, or rather

I believe we should say the *commencing recurrence*, of these sensations, which determines the repetition of the action. Thus the faculty of memory is essential to all strictly voluntary, as distinguished from instinctive, movements; and the experiments of Flourens and of Hertzwig instruct us, that it is the cerebellum, not the brain proper, which furnishes the physical conditions requisite for this recollection of muscular sensations.

Although there appears at first some difficulty in understanding how sensations which are only *anticipated*, or the *beginning* of which only is felt, can guide the contractions on which their perfect recurrence is to depend, we shall have no difficulty in conceiving this, if we recollect that it must necessarily be precisely in the same manner that a musician is enabled to go over any piece of music from recollection;—the anticipated sensation is, throughout that operation, the guide to the motion by which its own recurrence is to be secured.

In the performance of any such complex successions of muscular movements, we must allow that it is difficult to conceive that there is not only a continual transmission *downwards*, perhaps to different parts of the body, of certain definite nervous actions resulting from efforts of the will,—by motor nerves,—but likewise at least as many transmissions *upwards* by the sensitive filaments, of changes produced by the movements excited,—sensations thereby felt,—and mental determinations consequent on these, by which the successive volitions are guided. But it is admitted that, in all sciences, “reason can sometimes go farther than imagination can venture to follow;” and in no department of science can we more reasonably expect to meet with such examples than in tracing the actions of that exquisite mechanism, by which the sensations and powers of living animals are placed in connection with the world which is given them to inhabit.

But we may go a step farther, and understand more distinctly the mode in which sensations continually regulate and guide muscular actions, if we reflect on the phenomena to which Müller has very properly directed the attention of physiologists under the name of *consentient motions*, and of which the study of the eye furnishes us with some of the most instructive examples.

I need hardly say that this term is applied in cases where different nerves, and thereby muscles, are excited to action *simultaneously*, and where it is difficult or impossible to separate the combination. Such cases occur very frequently, both as to the strictly voluntary and the sympathetic or reflex movements, but especially as to the latter; and the following are the facts most important to be observed in regard to them.

* See Edinburgh Medico-Chirurgical Transactions, vol. ii.

1. The strictly voluntary motions thus simultaneously performed, are chiefly where the action that is willed requires considerable exertion, and is performed with difficulty. "Thus when we wish to contract the muscles of the external ear, we induce contraction of the occipito-frontalis muscle at the same time, without wishing it. During the most violent muscular action, many muscles act by association, although their action serves no apparent purpose. Thus a man making much exertion moves the muscles of his face, as if they aided him in lifting a load," &c.

2. In regard to most of the cerebral motor nerves, and nerves moving the trunk of the body, particularly when these act in obedience to sensation or emotion, the most important fact regarding their consentient action is, that this tendency is observed especially in the *opposite nerves of the same pairs*. Thus in the latter description of movements performed by the irides of the eyes, by the muscles of the face, by the pharynx, diaphragm, intercostal muscles, abdominal, lumbar, and perineal muscles,—in the actions of winking from bright light, of deglutition, breathing, coughing, sneezing, vomiting, laughing, sighing, weeping,—straining for evacuation of any of the viscera of the abdomen or pelvis,—it is certain, and is essential to the due performance of each action, that the corresponding portions of the nerves of the same pair, on each side of the body, should be affected, and should act on the muscles, exactly alike; and this is observed, even when the sensation exciting the movement is felt only through one nerve, and on one side of the body; as in the contraction of both pupils from bright light acting on one eye, or in the simultaneous and successive contractions of all the muscles of respiration, in consequence of a sensation excited in one of the nostrils, or one of the bronchiæ.

3. Another fact as to these consentient movements is satisfactorily observed *only in the eye*, but is no doubt extensively applicable in many parts, viz. that the stimulus of this consentient movement of voluntary muscles passes *through the ganglia*, and thereby affects muscles of strictly involuntary motion; the iris being distinctly observed to contract whenever the eyeball is voluntarily and forcibly rolled inwards by the action of the third nerve. And Müller relates experiments in his own person, distinctly shewing that this effect takes place even on the pupil of the right eye, in consequence of forcible voluntary exertions made through the third nerve of the left eye, and when the right eyeball is not moved.

I think it impossible to doubt that Müller is so far right in ascribing these phenomena to what he calls "the conducting power of the cerebral substance at the origin of the nervous fibres, whereby those which are con-

tiguous to each other are liable to be affected simultaneously, and the influence of the will (or of any mental act) is with difficulty confined or insulated on individual fibres," or something is required to insulate it; and that these observations put us in possession of an important fact regarding the influence, either of volition or of sensation, or of the changes in the nervous matter attending these mental acts, in exciting muscular action, viz. that this influence naturally extends to some distance in the larger masses of the nervous matter, and requires the action of some additional cause, to *insulate* it on individual muscles, or portions of muscles. And in so far as the motor influence dependent on sensation is concerned, this is strictly in accordance with what is observed as to the imitation of that influence, in experiments on the reflex function in paralyzed or decapitated animals.

I think Müller is also certainly right in supposing that the tendency to consentient movement in the similar or corresponding portions of any pair of nerves, is the reason why the third nerve is not employed to give the movement outward to the eyeball; two other nerves (the fourth and sixth) being employed to give this movement, because it is a movement which must always be consentient with that excited in a dissimilar part, and therefore through dissimilar nerves, on the other side of the body. And although this tendency to consentient motion is much less seen in the nerves of the same pair going to the extremities, yet Müller justly observes, that the extreme difficulty always felt in rotating one arm in one direction, and the other in the opposite at the same moment, must be ascribed to the violation implied in that effort of this tendency to consentient action in the corresponding portions of the same pairs of nerves.

But I think it also certain, particularly from what we see in the eye, that this observation goes but very little way in explaining the general phenomenon of consentience. The tendency to consentient action in the nerves of the same pair in any part of the extremities, is so slight, as to show that the conducting power at the origins of these nerves cannot be very strong, and, therefore, that proximity of origin can afford but a very imperfect explanation of the very strong tendency to consentience remarked in almost all the motions of the trunk of the body. Consciousness informs us that, although it is very difficult to act at the same moment on dissimilar portions of the same pair of nerves, yet there is in general no difficulty in refraining from acting at the same moment on the corresponding portions; and in no case any difficulty in acting, at the same moment, on dissimilar and distant nerves. And there are facts observed in the eye, which have

quite the value of the *experimentum crucis*, as showing that the chief cause of consentient movement in our muscular organs is very different from the connection of nerves at their roots or in their course. These facts are, that while those corresponding portions of the third nerve, which elevate and depress the eyeball, *i. e.* those which go to the superior and inferior recti, always act simultaneously, those which go to the rectus internus and inferior oblique do not usually act together in the two eyes. Again, the fourth and sixth nerves never act together on the two sides of the body, but each is uniformly combined in its movement with a portion of the third on the other side. The reason obviously is, that the *sensations* which result from the action of the fourth and sixth nerves of the one eye, cannot be identified with those which result from the action of the nerves of the same pair in the other eye, and cannot be separated from those which result from the action of that portion of the third pair in the other eye. There is no other circumstance, but the identity of the resulting and guiding sensation, which can be pointed out as existing where the consentience is observed, and not existing where it is not observed.

From these facts, therefore, we learn that the main cause of consentience of muscular movement is simply *identity of the guiding sensations*. Whether it is by an original instinct, or by repeated trials and acquired experience, that the acts of volition are directed to the nerves in each eye, which so turn the eyeballs as to keep the optic axis parallel, and so produce the single sensations, is a different question; but what has been stated seems to me quite enough to show, that it is because the single sensations result, that these nerves are consentient.

I have no doubt that this principle, deduced from the movements of the eyeball, is strictly applicable to all the cases of consentient movement excited by the nerves of the same pairs on the face, fauces, thorax, abdomen, and pelvis, in the different actions which have been already mentioned. The movements which these nerves excite are always followed by certain sensations, generally grateful, influenced by the degree in which the actions are performed; and by these sensations, the extent to which the actions are carried, and the energy with which they are performed, are felt to be habitually regulated. These resulting and guiding sensations are felt to be affected exactly alike by the movement which is excited on both sides of the body; and hence we instinctively carry the movement to the same extent in both.

It was a speculation of Darwin, that the actions of inspiration and expiration are originally determined by the uneasy sensation

of anxiety in the chest of the new-born child, leading to irregular and convulsive movements, out of which those are quickly *selected*, which are found by rapid experience to be effectual in appeasing that uneasy feeling; and although I do not agree to this statement, as expressing the order of events at that early period of life, and can assign no cause but instinct for the original selection of the proper nerves and muscles for this purpose, yet I believe that, at all periods of life, it is the sensation felt to result from the action of inspiration already in progress, which determines the energy with which it shall be performed, the extent to which it shall go, and even the number of muscles that shall be excited to partake in it.

And that this is the true account of the matter, we have farther and satisfactory proof, in the fact that in various cases of disease, particularly in cases of empyema, the contractions of the muscles of inspiration on one side of the chest become ineffectual for inflating the lungs, and for appeasing the sense of anxiety in the breast; in which case their nerves are no longer excited, and those muscles cease to act; they remain flaccid, and even, according to the observation of Dr. Stokes, they gradually become paralytic from inaction; a phenomenon, as I conceive, almost exactly similar to the loss of power in some of the muscles of the eyeball in cases of amaurosis affecting one eye.

II. Again, another important application of the information acquired by study of the nerves of the eyeball, is to explain the use of the plexuses or analogous contrivances, through which all the nerves, sensitive and motor, pass both to the upper and lower extremities, very generally in the animal kingdom.

In regard to the use of this very remarkable piece of structure, found in those nerves, by which the most forcible and the most nicely regulated muscular movements are effected, there have been various opinions. Several authors, among others Sir Charles Bell, have supposed it to be intended to facilitate the combinations of different muscles for particular actions, proceeding on the plausible supposition that, when the will acts simultaneously on several muscles, its influence proceeds from a single point, and is diffused from thence to those different muscles.

"The principal cause of the irregularity and seeming intricacy in the distribution of nerves, is the necessity of arranging and combining a great many muscles in the different offices. Wherever we trace nerves of motion; we find that before entering the muscles they interchange branches, and form an intricate leash of nerves, or what is called a plexus. This plexus is intricate in

proportion to the number of muscles to be moved, and the *variety of combinations* into which the muscles enter; while the filaments of nerves which go to the skin regularly diverge to their destination. From the fin of a fish to the arm of a man, the plexus increases in complexity in proportion to the variety or extent of motions to be performed by the extremity. By the interchange of filaments, the combination among the muscles is formed; not only are the classes of extensors and flexors constituted in the plexus, but all the varieties of combinations are there formed, and the curious relations established which exist between opposing muscles, or rather between the contractions of one class and the relaxation of another." In short, it appears to be his idea, that a plexus is necessary to enable a single effort of the mind to throw into action a combination of muscular contractions, and a succession of efforts to excite such a succession of these combinations as exists in every complex movement.

But the case of the muscles of the eyeball seems quite sufficient to set aside this opinion. None of these nerves on the opposite sides of the body are connected by plexuses, yet no nerves can combine their actions more perfectly or more surely. There is no more perfect consentience in the living body than that between the sixth nerve of the right eye, and the inner portion of the third of the left, and both are often exerted in varied combinations with many other nerves and muscles; but no nerves in the body can have less connection, so far as anatomy informs us, either at their origin or in their course.

In fact, when we reflect on what passes within us when we throw into action any two muscles at the same moment, we shall see that when such a voluntary effort is made, it is just as easy for us to excite simultaneously the most widely distant or the most closely contiguous muscles; and again, when we attend to the necessary *selection* of so many different and distant muscles, in any of the requisite combinations which are apparently under the influence of sensation, as in coughing, sneezing, vomiting, &c. we shall perceive that, in the entire state of our faculties, any intense sensation may be said to have at its command all the muscles of the body; and although, as I have stated, I believe all mental acts to be guided by sensations in the selections which they make, yet I think it quite plain that neither proximity of origin, nor connection in their course, can be assigned as the cause of any of these selections.

I believe that Dr. Monro made a nearer approach to the true statement of the use of a plexus, and put it in a simpler view, when he said, that "the chief intention of nature in this very solicitous intermixture of the

nervous fibrils, is to lessen the danger by which accidents or diseases affecting the trunks of the nerves would, without these contrivances, have been attended. Thus let us suppose that two nerves are sufficient to supply the flexors and extensors of the forearm, it is evidently better for us that the one-half of each nerve should go to the flexors, and the other half of each to the extensors, than the whole of the first nerve should have gone to the flexors, and the whole of the second to the extensors. For if by accident or disease one of these nerves should be cut across, or lose its powers, we should, on the first supposition, preserve one-half of the powers, both of flexion and extension, which would surely be preferable to our possessing fully the power of flexion without any power of extension. And thus, in the arm, where five trunks are found, there would on this supposition, as to the use of a plexus, be only one-fifth of the power lost, of performing any motion, by division of any one of these nerves." (Obs. p. 45.)

That this is really the effect of this arrangement in regard to the effects of injury, appears to be sufficiently established by the experiments of Panizza on frogs, in which animals the plexus supplying the inferior extremities is much less intricate than in the mammalia. "If," he says, "one anterior root of the three last spinal muscles be cut, the motions of the corresponding extremity are as perfect as if the motiferous nervous system of the part had not been injured. Even if two roots be divided, although for a moment the motions are not so energetic as at first, yet they are speedily renewed, and the frog springs as if it had suffered no injury. Yet, by this operation, more than two-thirds of the nervous matter which presides over the motion of the extremity is destroyed; and if the third filament is divided, all motion immediately ceases in the limb." "Whence, if I am not mistaken, appears the use of the nervous plexuses, which, by the intermixture of the filaments of different roots having a common function, establish among them, as it were, such a concentrated force, that each is adequate to preserve the integrity of the function, when, by means of any harm, the continuity of the other filaments is interrupted." (Edin. Med. and Surg. Journal, No. 126, p. 89.)

I am aware of experiments by Cronenberg and by Müller, who found that by cutting one of the nerves entering the crural plexus in the frog, they could paralyze or greatly enfeeble certain movements of a limb, and leave others unimpaired; and of the elaborate investigations of Müller and others in Germany, which lead to this conclusion, that every nervous fibril, whether passing through a plexus or not, remains perfectly distinct

from its origin to its termination. Notwithstanding these observations, it is distinctly admitted by Müller, that "plexuses convey to each muscle of a limb fibres from different parts of the brain and spinal cord."

It seems to me, however, hardly possible to suppose, that this very carefully adjusted piece of structure is intended merely as a guard against injury, and therefore is of no use in any person or animal on whom such an injury as the section of one of the nerves of an extremity has never been inflicted. But if we advert to what has been said already of the evidence that any voluntary effort, which excites a muscle to contraction, extends its influence over a *considerable portion* of the cerebro-spinal axis, and at the same time to the evidence, in the experiments above quoted, that every muscle supplied from a plexus has part of its motor nerves, and may be excited to contraction, from each of the nerves entering that plexus, we can hardly miss the conclusion, that this contrivance not merely provides against injury, but *multiples the power* which acts on each of these muscles, and enables the mind to *vary* the degree of energy which it can expend on each, in a degree much greater than in any case where it can act on a muscle only from a single point of the spinal cord.

Then, if we remember farther, that, by means of the plexus, each *sensitive* nerve which supplies any muscle of the extremities, consists of fibrils coming from different points of the cord, we can easily perceive that, by this arrangement, the sensations resulting from each portion of the muscle may be more distinct, and more easily discriminated from each other, than those which are excited by nervous fibrils bound in the same sheath throughout their course, and originating beside each other in the cord.

Thus the effect and use of a plexus will be, to make the muscular sensations more precise and distinct, and to make the power which the will can exert over the muscles greater, and capable of greater increase at pleasure, than where such arrangement does not exist; and therefore, to increase the force and precision with which the efforts of volition may be directed and insulated on the muscles which are thus supplied with nerves. And I think that any one who attends to the subject may observe that he is actually conscious of these differences, when he compares the effects of his voluntary exertions in his extremities with the motions of his head and trunk.

I think, therefore, that Sir Charles Bell was right in asserting that the plexus enables the acts of the will to form combinations of muscular motions for definite ends, in greater variety and with greater precision than they otherwise could: but I apprehend

the reason to be, not that each combination is effected by an impulse emanating from a single point, nor that the different combinations are *formed* in the plexus, but that the plexus, rendering the muscular sensations more distinct, and the acts of the will more energetic, enables the mind to act on all the muscles thus supplied with more power and precision, and to recollect and resume the action at any subsequent time with more certainty and uniformity, and thus facilitates combinations.

[To be continued]

PLURALITY OF CHILDREN AT BIRTH.

To the Editor of the Medical Gazette.

SIR,

SEEING in your valuable journal of last week a case reported by Dr. Henry Davies (whose pupil I formerly had the honour of being) of a plurality of children at a birth, I am induced to forward you an account of two similar cases that occurred in the practice of a medical gentleman (Mr. Woods) of this town, who has kindly presented me with the placenta of one, and the particulars of both, should you think them worthy of an insertion.—I am, sir,

Your obedient servant,

CHARLES DODD, Surgeon.

Northampton, May 17, 1841.

Mrs. Manton, æt. 32, mother of seven children, with none of which did she go to the full period of utero-gestation, was taken in labour at 4 P.M., Nov. 20, 1840, having been pregnant between six and seven months. She did not send for the medical gentleman till 1 A.M., Nov. 21st; and on his entering the room, the nurse said, "Sir, the child was born with the pain you heard as you came up stairs." On examination, one child, a male, was found in the usual situation; another, a female, between the thighs; and the third, a female, against the abdomen: the woman described them as all being born with one pain: the placenta was expelled naturally, and the woman recovered without a bad symptom. The male child lived half an hour, one of the females 36 hours, and the other a month. The placenta, which I have now in my possession, is in one mass; between two portions there is no membranous septum, but there is a very distinct membrane between these and the

third portion. I injected the placental vessels of each child with different coloured wax, and there is evidently no communication between them.

In the other case, which occurred to the same gentleman about ten years since, the first child was expelled naturally, but the other two were footling presentations: the placenta came away in the usual time, and was also in one mass, but it was not injected. Here, however, there were three distinct membranes: the woman did well, but the children all died in a few days.

ON STAMMERING,

AND THE METHODS PROPOSED FOR ITS REMOVAL.

By EDWIN LEE, Esq.

[Continued from p. 352.]

[*For the Medical Gazette.*]

I now proceed to the consideration of the operations which have been performed for the cure of stammering, and of their respective applicability to particular cases.

The first operation for stammering was performed by Professor Dieffenbach, of Berlin, in January last, who, in a letter addressed to the French Institute, thus states the manner in which he contemplated the removal of the complaint might be effected:—"As I conceived that the disorder in the mechanism of speech produced by stammering was referrible to a dynamic cause, which I considered to depend upon a spasmodic state of the air-passages, especially of the glottis, which was communicated to the tongue, muscles of the face, and even of the neck, I was led to think that by interrupting the innervation in the muscular organs which participate in this abnormal state, I should succeed in modifying or preventing it altogether." Accordingly he proposed the transverse section of the muscles of the tongue by three different methods; first, transverse horizontal section of the root of the tongue; second, transverse subcutaneous section of the root of the tongue, or section of the muscles without division of the mucous membrane; and, third, the horizontal section of the root of the tongue, with the excision of a triangular portion throughout its

whole width and thickness. In performing these operations, the tongue is seized with forceps terminating in double hooks to each blade (*pince de Museaux*), and drawn out of the mouth. A bistoury is then passed through it at its thickest part from one side to the other, and its substance divided by cutting upwards. The posterior part is immediately seized with forceps, and held by an assistant, while the operator passes through it from behind forwards three short curved needles, armed with strong ligatures, which are carried to the bottom of the wound, and brought out on the upper surface of the anterior portion, when they are tied together and approximate the cut surfaces. The second operation is performed in a similar manner, with the exception that the mucous membrane of the dorsum of the tongue is not cut through. In the third, a piece of the tongue is cut through, somewhat resembling in shape a slice of melon, and the ligatures applied as in the first method. This last operation has entirely superseded the others, which were only performed at the outset.

The first operation was performed in four cases; in one, where there was a paralytic state of the tongue, it was unsuccessful; in the other three it was attended with success. The patient first operated upon was a boy whose stammer was very bad, and who had been considered to be incurable. He experienced more especially a difficulty upon the gutturals *g, k, ch, z*, and other consonants. At times he could not speak; and the presence of strangers always produced considerable agitation. The tongue was rigid to the feel; and the action of the muscles of the face and neck was considerable. On attempting to speak, the first word always caused the greatest difficulty: after this was overcome he could speak easier, and the words issued out in quick succession, till, on his becoming confused, the stammer returned. There was a good deal of hæmorrhage during the operation; but it ceased after the ligatures were tied. The stammering was removed, but the contractions of the face continued when he spoke. Considerable swelling of the tongue, and fever, supervened, which, however, subsided, and on the seventh day from the operation no remains of stammering were perceptible; the convulsive

movements of the face and lips had disappeared; his pronunciation was easy; the presence of strangers or mental emotion did not occasion any recurrence of the stammer. In the case where the second method of operating was adopted, on the introduction of the bistoury the blood gushed out with violence on both sides, and the tongue became very considerably swollen from the extravasation of blood. The third operation was performed on a boy, æt. 16, who had great difficulty in pronouncing words beginning with certain consonants, and also occasionally upon the vowels, attended with considerable spasmodic action of the muscles. When with his brother and sister he could frequently speak very well; but the least agitation, or the presence of strangers, caused a recurrence of the stammering. A slice of the tongue was cut out, and a good deal of bleeding ensued. The stammer was, however, removed, and, on the eighth day, the cure was complete.

The Paris papers having mentioned that a letter had been received, on the 9th of February, from Professor Dieffenbach, stating that he had operated successfully upon the muscles of the tongue for stammering, though the nature of the operation was not mentioned, several surgeons began to operate. M. Phillips first performed the operation of dividing the *genio-glossi* muscles below the tongue in private, and sent a sealed packet to the Académie des Sciences descriptive of the method he had adopted, and the result. I saw the patient at his house, a few days afterwards: he could speak and read with considerable facility. M. Velpeau, however, first operated in public, after describing the operation, on the 14th February. M. Amussat, who had directed his attention to the subject (before notice of Dieffenbach's operation had arrived) in consequence of a patient stammering who presented himself to have the operation for squinting performed (which was likewise the case with Professor Dieffenbach), after having examined the muscles beneath the tongue in this patient, stated to several persons present his opinion that their division would be likely to relieve the stammer. He subsequently performed the operation on several patients, some of whom were presented to the Académie de Médecine.

M. Baudens and others likewise operated with success in many cases.

M. Phillips' operation is as follows:—The patient seated on a chair, his head resting on the breast of an assistant, the operator seizes the frenum with a small hook near its angle of reflexion with the tongue. Another hook is inserted a little lower down, and an incision with scissors made between the two, and the membrane divided to some extent on either side; a sharp-pointed curved bistoury is then introduced, and, carried from one side of the symphysis of the jaw to the other, dividing the attachments of the muscles. The bleeding is sometimes abundant, but is salutary. A piece of sponge dipped in vinegar is placed in the wound to arrest the bleeding.

M. Baudens plunges a pair of finely-pointed scissors, curved almost to an acute angle, with their blades moderately separated, beneath the tongue, immediately behind the symphysis of the jaw, and with one cut divides the attachment of the *genio-glossi* muscles. There is generally little bleeding, as the incision is made close to the bone. A piece of sponge soaked in vinegar is put into the wound, and retained for two or three days, which practice has, in some instances, given rise to inflammation and suppuration. M. Baudens likewise divides the *genio-hyoidei* in those cases where the muscles of the neck and throat are implicated in the spasmodic action. One of the worst cases of M. Baudens was that of Vincent Zousset, a baker (*boulangier*) who was unable to articulate his name or profession. Immediately after the operation he could pronounce these words with great facility.

M. Amussat divides his operation into two periods or parts. The mouth being opened wide, and the tongue turned back, the mucous membrane of the lower part of the frenum between the Whartonian ducts is cut with small scissors, and the incision is extended on either side, the tongue being at the same time drawn outwards, so as to expose the *genio-glossi* muscles, which are then divided with large scissors curved on the flat. "At the point," says M. Amussat, "where I practise the section of the *genio-glossi* muscles, there is less difficulty and danger than at any other. You act on a double fibrous band (*faisceau*) or on

the summit of the triangle, whilst higher up, as is well known, the muscles spread out in a fan-like form, and are surrounded by vessels and nerves."

In some individuals it is found that the mere section of the frenum and sublingual membrane on either side of the roof of the mouth is sufficient to remedy the infirmity. Thus, out of fifty-five persons who were operated upon, eighteen were relieved in this manner. There is not in general much bleeding, and in none of the above cases has it occasioned uneasiness; when more than usually abundant, it is stopped by iced water and small lumps of ice beneath the tongue.

One of the first patients operated on was Alexis Beyeuval, a man, *æt.* 48, who had stammered from his childhood, and had had the frenum divided at two different periods without any advantage. The stammer was of the worst kind. The movements of the tongue were very limited. It was turned towards the right side, and the patient could not protrude it over the upper lip. After the division of the frenum and the sublingual membrane on either side, he could speak some words plainer than before, but experienced great difficulty upon others. The *genio-glossi* muscles were then divided, which was followed by considerable amelioration, though the stammer was not altogether removed. Some muscular fibres which were felt to be still attached to the bone were cut through, and pronunciation became free and easy, with scarcely any remains of the stammering. The deviation of the tongue was likewise rectified. Two months afterwards (18th April) there had been no relapse; the patient spoke as well as immediately after the operation.

Victoire Courgeot, *æt.* 16, has stammered since her childhood; her elder sister likewise stammered till she attained the age of fourteen, when it ceased. The father of these girls was a stammerer, which strongly corroborates the opinion I have already advanced; viz. that the majority of cases of stammering in females would be found to arise from imitation. We see, in this instance, that the sister, when approaching to puberty, being probably less under the control of her father, and associating less with him, lost her stammer; whereas, in the majority of

cases, the complaint increases at this period of life. In Victoire's case the division of the membrane was sufficient to cure her. Two months afterwards there had been no relapse.

An operation of a different kind was performed by M. Velpeau a few days before I left Paris. In this patient the tongue was larger than natural. He could touch the lower part of his nose and chin. A small triangular portion was cut out of the apex of the tongue, without dividing the mucous membrane beneath. The edges of the wound were brought together with points of suture. This was attended with some degree of amelioration at the time; but I hear that as the wound healed the stammering returned, though not so bad as before.

Another method which I saw described a few days ago in the *Gazette des Hôpitaux* has lately been tried, as it would appear with success, by the same eminent surgeon. The patient was a young man from whom scarcely a word could be obtained, inasmuch that he would have been considered dumb, were it not that the movements of the lips, and the violent efforts which he made to articulate, indicated his actual condition. The tongue in this case was also very long, and he could touch with it the lower part of his nose. Previous to operating, M. Velpeau tried the experiment of raising the tongue with a pair of ordinary forceps, when the patient was able to pronounce some words; from which it was anticipated the operation would be attended with success. The operator then drew the tongue out of the mouth with his left hand, furnished with a piece of linen rag, and with the right passed transversely through its substance, at the junction of the posterior and middle thirds, a needle armed with four ligatures. Two of the ligatures were tied as far back as possible; the other two were tied anteriorly, thus circumscribing a portion of the tongue, which, after it had sloughed away, would entail a similar loss of substance as in Dieffenbach's operation. The patient did not appear to suffer much, and, immediately after the operation, was able to pronounce some words distinctly. He would not remain in the hospital, but promised to return every second day. During the first four days the size of the tongue was considerably

enlarged, and the neighbouring parts were swollen, but no serious accident ensued: a few leeches, with the use of gargles, sufficed to allay the above symptoms. A week after the operation there was only some slight inconvenience felt in the throat. The stammer was in great part removed, so that he could speak with tolerable facility.

About the same time M. Velpeau tied the temporal and facial arteries on a man, æt. 36, affected with epilepsy during the last seven years. The disease was first induced by a fright, and the attacks had continued eight or ten times a month: but within the last three months he had attacks almost daily. The temporal arteries were first tied: the patient had only a slight attack on the same day, and the following day passed without any. On the 5th of April the external maxillary arteries were tied at the point where they pass over the jaws, and the attacks did not recur.

The operation on the *genio-glossi*, as performed by Mr. Lucas, does not differ materially from the other methods which have been already mentioned, except that a portion of the muscle is removed: but a different mode of dividing these muscles, viz. the subcutaneous, has more recently been practised by M. Bonnet, of Lyons. A puncture is made in the skin, a few lines behind the symphysis of the jaw: a blunt-pointed tenotome is then introduced, with its sharp edge turned towards the bone, and passed upwards till its point is felt by the finger through the mucous membrane beneath the tongue. The attachments of the muscles are then divided right and left; the cutting edge of the tenotome being kept close to the bone, and acting only on the superior part of its concavity, the *genio-glossi* are alone cut, and the *genio-hyoidei* avoided. Scarcely any bleeding ensued. M. Bonnet had performed this operation in five cases: the two last patients, though labouring under a bad form of stammering, and who even stammered in reciting verses, were immediately relieved without preserving the least trace of their infirmity. On the other three patients the relief was not so decided, though a considerable degree of amelioration resulted; which circumstance M. Bonnet ascribed to the mode of operating not being so perfect in the first cases as in the last:

though I should think it depended on the former being more strictly cases of nervous stammer than the latter, and that the operation would not be so likely to be permanently successful.

The following cases will serve to illustrate the two varieties of stammering.

Purely nervous stammer.—A young man who has stammered since his childhood, states himself to be very nervous. When alone, or when with persons with whom he is very intimate, he can talk very well, but almost always stammers before strangers; sometimes more than at others; especially if he thinks the infirmity is remarked, or if he be questioned respecting it. The stammer is not, however, very bad. There is no particular tension of the muscles of the tongue, which can be turned upwards towards the nose, nor is there any thing anomalous perceptible about the mouth or throat. He has two cousins similarly affected.

Physical stammer.—This man always experiences difficulty in pronouncing certain words, especially those beginning with a q or n, as *quatorze, navet*; considerable spasmodic action of the muscles of the face and lips being induced by the attempts to articulate these or other words upon which the difficulty exists. He has as much difficulty when alone as when in company or before strangers: cannot protrude the tongue far, or turn it upwards over the lip. After the division of the sublingual membrane, and cellular texture on the floor of the mouth, he was able to protrude the tongue, and could speak the above and other words with facility.

Mr. Yearsley's operation consists in the excision of the entire uvula, and also of the tonsils, when these bodies are enlarged or diseased. The part to be removed is seized with an Assalini's tenaculum, and cut off, scissors being employed for the uvula, and a knife for the tonsils, which, being frequently hardened, present considerable resistance, and could not, in all probability, be cut through by the new instrument, or guillotine as it has been termed, recently invented for this purpose, on the supposition of the likelihood of hæmorrhage from this operation; which occurrence, though it might happen when the tonsils are enlarged and soft, is not likely to take place, and I believe never has happened, when they are indurated. The extirpation of these parts

is attended with scarcely any pain in most instances, and the pain from the excision of the uvula is but slight. Nor has any particular inconvenience, as far as I know, attended the loss of this part; though it is said that singers and others, who have had this operation performed, were more liable to sore-throat and coughs. Mr. Yearsley, however, states that this is not the case when the entire uvula is removed; but that when only a portion of it is snipped off the pain is much greater, and subsequent irritation is not uncommon, which may be very easily conceived. In some cases, when the palatine arch descends lower than natural, it is snipped on either side previous to the removal of the uvula.

One of the most successful cases of this operation which has fallen under my observation is that of Crawley (the seventh case in Mr. Yearsley's pamphlet), who was affected with one of the worst kinds of stammer; in whom the tonsils and uvula were enlarged, and who derived immediate relief, which has continued to the present time (two months from the operation). He can now speak with facility, and without stammering.

In the boy Wright the stammer came on when he was between three and four years of age; there were occasionally remissions of a few weeks at a time; and as he had not stammered for a long time, his mother supposed that he had got rid of it altogether. Three months ago, however, his father died, which occasioned a recurrence of the stammer. Nothing abnormal was perceptible about the mouth or throat. On the uvula being removed he immediately spoke freely, and without impediment. I am unable to say whether, in this case, the relief was permanent.

A man, æt. 40, sailmaker, when alone speaks "as well as any body;" and when with his comrades does not stammer so much as when with strangers, when the inconvenience is sometimes very great. Does not stammer when he speaks in a singing voice. The uvula was removed, but he still stammered, though not so much as before.

A man named Partridge has a difficulty, especially upon the p's, and can scarcely articulate his own name; but if he says it without forethought, or if

his attention be diverted, can speak it very well.

Snelling, a young man who was in the room when the boy Wright underwent the operation, on seeing its effect, and that the boy spoke without difficulty, was likewise able to speak without stammering. At my suggestion he was sent back to wait a little, and on returning into the room, at the expiration of about an hour, stammered a good deal while being questioned respecting it. There was a warty excrescence on the left tonsil: while he was asked about its origin he spoke fluently, and without the least stammer. This was also the case when questioned about other things which diverted his attention from the complaint. After the wart was removed he thought he spoke better, but still stammered. After removal of the uvula he spoke better, and on reading experienced every now and then some difficulty.

A boy, who had more especially a difficulty on letters beginning with p and l, experienced considerable hesitation when told to say *lore-child* or *lollypop*; but after a full inspiration he could pronounce these words tolerably well during the act of expiration. After the removal of the uvula he could articulate them with facility, and without drawing in his breath.

A young woman, whose uvula was removed without any perceptible advantage.—The muscles beneath the tongue were a good deal developed, and this organ appeared to be limited in its movements. She is not free from stammer even when alone, but is always much worse when with strangers.

A man, in whom the palate had been extensively divided by another surgeon without any advantage resulting.—The uvula was excised by Mr. Yearsley, but did not produce any amelioration at the time.

Henry Gee, a bad stammerer.—The palate was divided on one side, after which he spoke better. Desired to return in a week. At the expiration of this period he still stammered, though not so badly as before. His mother says that he spoke better the two days succeeding the operation than the three subsequent days. After the uvula was removed, he was able to articulate much easier than before.

Wilkinson (mentioned in Mr. Yearsley's pamphlet), a man in whom the tongue was

of large size.—Uvula removed without any advantage.

Henry Smith, a boy who stammered.—The tonsils were enlarged. After their excision was able to speak without much difficulty. The uvula was next removed, but it did not appear that he spoke any better than after the operation on the tonsils.

The above are a few of the cases of which I made a memorandum, and to which I shall have to allude. It now remains that I should endeavour to explain in what manner these various methods and operations were successful in removing stammering, and the causes of their failure in some instances; and to what cases the one or the other are more particularly applicable.

[To be continued.]

CONGENITAL APERTURE IN DIAPHRAGM.

To the Editor of the Medical Gazette.

SIR,

A FEW days ago a case of congenital diaphragmatic hernia occurred to me, a brief account of which may not be uninteresting to your readers.

A lady, thirty years of age, was confined with her second child at the full period of gestation, after a short and easy labour. The respiration of the infant was very imperfect, and it died an hour after its birth. As nothing existed in the circumstances of the labour to account for this result, I expected some malformation or disease in the chest, and requested permission to examine the body. There was found a large opening in the central tendon of the diaphragm (from arrest of development) through, which the whole of the small intestines, and a considerable portion of the liver, had passed into the right side of the chest, occupying the greater part of that cavity, and unconfined by adhesions, so that the whole could be withdrawn through the same opening. The right lung was a mere vestige, and lay close against the spine, in texture resembling the carnified lung in empyema. The left lung was very small also, but permeated by air throughout, which rendered every portion of it buoyant, even after forcible compression. The heart and primitive vessels were of normal size and struc-

ture. The child was a male, of average size, and the presentation was natural.

I believe the cases on record of a similar nature are rare; perhaps they would be less so if medical men made a point of opening the bodies of all still-born children. The examination in the present instance was very satisfactory to the parents as well as myself.

I am, sir,

Your obedient servant,

W. F. MORGAN,

Surgeon to the Bristol Infirmary.

15, Park Street, Bristol,
May 18, 1841.

A CASE OF POISONING BY OPIUM,

IN WHICH ELECTRICITY WAS EMPLOYED
WITH SUCCESS.

By JOHN ERICHSEN, Esq.,

Formerly House-Surgeon to University College Hospital.

(For the Medical Gazette.)

CASE.—Sarah Mitchell, ætatis 22, was brought to University College Hospital about 2 P.M. on the 6th of August, 1840, labouring under the ordinary symptoms of poisoning by opium. The friends accompanying her said that they knew but little concerning the particulars of the transaction; that she was a married woman, and appeared to live on good terms with her husband; that on visiting her rooms about two hours ago, they found her in a very "stupid" state, and scarcely able to answer any question put to her: she however informed them, that having procured laudanum at different shops to the amount of an ounce, on the plea of its being required as an application to an aching tooth, she had swallowed it with a view of putting an end to her existence, and that she was then labouring under the effects of the poison. A medical man who was called in gave her an emetic, which induced vomiting, and advised her being sent to a hospital, which was accordingly done.

On admission, four hours after taking the poison, she was perfectly insensible; her countenance was flushed, or rather had a blotched appearance; the surface of the body and the hands were cold and clammy; her eyes were closed, and the pupils were firmly contracted; her limbs were flaccid; she was not able to

walk, and answered no questions, even when put in the loudest voice; her pulse was slow and small, and her breathing less frequent than natural, but without any stertor.

Immediately introduced the stomach-pump, and drew off a small quantity of fluid impregnated with the odour of opium, and then washed out her stomach with warm water, until it came away quite clear. In order to rouse her, hot strong coffee, with brandy and ammonia, was given; and large quantities of cold water were repeatedly and forcibly dashed in her face. She was also, without intermission, dragged about a cool room between two men; and was occasionally rather roughly shaken and slapped on the back: *dolichos pruriens* was applied to her hands and feet.

The cold affusion roused her for a time, to a certain degree, but she almost immediately relapsed into her drowsy condition: none of the other means that were employed had any effect upon her.

About three hours were spent in this way, when, instead of getting better, she appeared to become more comatose, and it was only with very great difficulty indeed that she could be roused at all.

Being fearful of losing her, and thinking that a stronger stimulus than any that had as yet been employed was required to overcome the state of torpor in which she was, I determined upon trying the effect of electricity. For this purpose a rather powerful electromagnetic apparatus that was in the hospital was set in action; one of the cylinders, which was attached to the conducting wires, being applied to the forehead, and the other to the upper part of the spine. After a few shocks had in this way been passed through the head, she began to recover from the state of coma in which she had previously been, and attempted to remove the wires with her hands, begging that the shocks might be discontinued, as they gave her pain. They were, however, persevered in for about twenty minutes, or half an hour, when she was sufficiently recovered to be able to answer questions with comparative facility, and to walk a little. She was then removed to the ward, and allowed to lie down, with strict injunctions to the nurse, however, to prevent her sleeping, by continuing the admi-

nistration of the coffee, and by shaking her occasionally. Towards the evening she became quite sensible, cried frequently, and deplored her present condition.

7th.—Has passed a good night; complains of some pain at the pit of the stomach, but has not vomited. Has a nervous tremor about her. Pupils not so much contracted, but as yet not fully dilated. She feels cold and weak; pulse sharp, but not quick. Her bowels have been opened by a dose of castor oil. Dr. Thomson saw her in the course of the afternoon, and ordered a saline draught every four hours.

8th.—Much the same as yesterday; bowels confined.

Infusion of Senna with Salines ordered.

10th.—Complains of pain in the lumbar region; the nervous tremor exists to a great degree; pulse is quick and irritable; bowels confined; she has not passed any water since yesterday afternoon; there is great tenderness on pressure at the epigastrum. Dr. Thomson ordered

C. C. Lumbis ad ξ xij.

R Pil. Hydrarg.; Ext. Aconiti aa. gr. j. .
Ext. Gentian. gr. iij.; Ft. Pilula 6ta
qq. horâ Sumenda.

R Decocti Aloes, ξ iv.; Tr. Valerianæ
Vol. ξ ij.; Misturæ Camphoræ. ξ ij.;
Sumat. Atam partem inter singulas doses
pilularum.

12th.—Has much pain in making water, which is scanty; she still complains of some pain in the loins, which has, however, been relieved by the cupping; pulse very tremulous, and quick; general tremor over the body: all the symptoms of poisoning have disappeared, and she is now labouring under hysteria produced by great agitation of mind. Surface clammy and perspiring; does not sleep well; bowels somewhat confined.

C. C. Lumbis ad ξ xij.

R Pil. Hydr. gr. v.; Ext. Conii, gr. iij.;
Ft. Pilula; quamprimum sumenda;
Haustus Niger horâ unâ post pilulam.

14th.—Patient is very much better. She has entirely recovered from the effects of the poison, and has nearly lost all the hysterical symptoms.

16th.—Discharged cured.

In another case of poisoning by opium which was brought to University College Hospital about six weeks ago, my friends, Dr. Lankester, the resident

medical officer, and Mr. Henry Taylor, one of the house-surgeons, employed electricity with success after all other means had failed. I have not the particulars of this case: but I believe they will shortly be published in one of the journals.

REMARKS.—My object in publishing these cases has been to direct the attention of the profession to the employment of electricity as a powerful means of rousing the energies of the nervous system in cases of poisoning by opium; more especially as it is a mode of treatment that, I believe, has not been hitherto recommended by any writer on toxicology; at least I have not found any mention made of it in any work on that subject which I have had an opportunity of consulting.

The chief indication to be fulfilled in the treatment of poisoning by opium is, after the stomach has been emptied by means of the stomach-pump, to keep the nervous system roused until the narcotic effects of the drug wear off, which happens after a longer or shorter time, according to the size of the dose taken and other modifying circumstances, just as the excitant effects of a stimulant, such as alcohol, gradually pass off. Now we are certainly in possession of no stimulus which is so immediate in its action, so powerful, and so easily applied, as electricity. In all these respects it is far superior to dashing cold water on the body and face. Moreover, the cold affusion, if continued too long, may be productive of some injurious effects; for, if the patient be allowed to remain any length of time with his clothes saturated with water, the cold, by depressing still more the energies of the system, will tend to aid rather than to counteract the sedative influence of the opium. It should therefore be employed with great caution in those cases in which the surface is cold, the pulse slow and weak, and the respiration feeble. It is quite possible for pneumonia to follow the use of the cold affusion: this actually happened in the second case which I have briefly mentioned above; the disease, no doubt, being predisposed to by that congested condition of the lungs which is so common a consequence of narcotism. Notwithstanding these objections to the employment of the cold affusion, it is, if properly used, a most valuable means in the treatment of

poisoning by opium, and one that, in the great majority of cases, is fully sufficient to overcome the narcotic effects of the poison, after the exciting cause has been removed from the stomach. In some instances, however, of which the case detailed above is a good example, the shock produced by the sudden and forcible dashing of cold water is not sufficiently powerful; and it is in this case that I would strongly recommend the employment of electricity after the cold affusion had been persevered in for a moderate length of time, from half to three quarters of an hour, and had failed in rousing the powers of the patient.

The electricity should not supersede the use of the cold affusion, or of those other means that are ordinarily resorted to in cases of poisoning by opium; but that it may be employed with the greatest advantage in addition to these, I think we are fully warranted in concluding from the case that I have detailed, and which, there can be little doubt, would have had a fatal termination had it not been for the employment of this very powerful stimulus, which produced a most marked and almost immediately beneficial effect; the patient, who was quite speechless, insensible and motionless, with flaccid, cold, clammy extremities, and a small weak pulse, attempted, after a few shocks had been passed through her head, to remove the wires, complaining of the pain the application of the electricity gave her: and was in half an hour sufficiently recovered to answer questions that were put to her, to walk, and to be allowed to lie down on her bed.

LIGATURE OF COMMON CAROTID.

To the Editor of the Medical Gazette.

SIR,

I BEG to inclose you the notes of a case of aneurism on the side of the face, cured by tying the common carotid artery. The case was extremely interesting to me at the time of its occurrence, and I think may probably be so to the profession at large.—I am, sir,

Your obedient servant,

JAMES SURRAGE,
M.D. M.R.C.S.

Wincanton, Somersetshire,
April 20th, 1841.

Monday, October 26th, 1840.—John Churchouse, a tailor, aged nineteen,

called on me this day to consult me respecting a large tumor on the left side of the face. About a year since, when cutting one of the dentes sapientiae, he perceived a hard swelling behind the jaw, but, as he associated its existence with the state of the tooth, he did not at the time attach much importance to it. From the above period, however, it gradually enlarged, and, during the last four months, has increased very rapidly, but without much pain. Since the case has been in progress the patient has consulted several surgeons, who have given him different opinions as to its nature; some considering it a chronic abscess, whilst others thought it a disease of the bone, and recommended him to place himself in some hospital. The tumor, when I first saw it, was of an immense size, extending from below the angle of the jaw upwards, until it was lost behind the malar bone, and from the ear forwards to within an inch of the mouth; it was cedematous over the whole surface, and firm beneath, but neither pulsation nor fluctuation could be detected. The patient could not breathe through the left nostril, and the right felt greatly obstructed. On examining the mouth, which it was difficult to do, in consequence of the confined state of the parts, I found the cheek pressing inwardly against, and much indented by, the teeth; the molar and first bicuspid of the upper jaw were, indeed, nearly hidden by the gums, and the mucous membrane on the left side of the palate projected so much as to resemble very strongly the pointing of an abscess. After carefully reflecting on the history of the case, and under the hope that by doing it I should gain an insight into the nature of the swelling, I determined on extracting the tooth supposed by the patient to be the original cause of the mischief. It was not decayed, or unnatural in appearance; nor was its extraction followed by a discharge of matter, or more bleeding than usual. About twenty-four hours after the tooth was removed, I was summoned to the patient in consequence of considerable hæmorrhage from the socket: this was easily stopped by a plug of lint, but recurred in the course of eight hours to a very considerable extent, and produced alarming exhaustion. The tension of the tumor being now much lessened, an indistinct pulsation

could be felt, synchronous with the pulse at the wrist, and removeable by pressure on the carotid, so that the nature of the case was no longer doubtful. The patient now, for the first time, told me he had been subject lately to bleeding from the left side of the nose, and that twice within the fortnight epistaxis had occurred to an alarming extent; so much so, indeed, that, on one of the occasions, severe syncope came on, and continued for a considerable time. There could now be no doubt the case was one of aneurism, either of the external carotid, or one of its terminal branches; most probably, I think, of the internal maxillary. I therefore determined on tying the common carotid. My friends, Mr. Eastment and Mr. Bruerton, whom I now consulted, coinciding with me in opinion as to the nature of the case, I availed myself of their ready assistance, and immediately performed the operation, on the morning of the 28th, two days after I first saw the patient. The vessel was secured in the usual manner, and without much difficulty, about a quarter of an inch below the tendon of the omohyoid muscle.

Vespere.—The tumor considerably diminished in size, no pulsation, and the patient comfortable; there was some oozing of bloody saliva from the mouth, which continued, at intervals, until the evening of the 30th, when several coagula came away, and there was a discharge of arterial blood to the amount of four ounces. The swelling was now materially lessened, being not more than half of its original size; but, as I was fearful of hæmorrhage, I plugged the opening in the mouth with lint, kept the head supported, and the cheek constantly moist with evaporating lotion.

Nov. 3d.—The tumor has been gradually increasing since my last report; there is now considerable pain and throbbing; the cheek is hot, and wears a hectic appearance. As it was evident the sac was suppurating, I removed my plugs, and gave exit to about two ounces of grumous blood, mixed with pus; the swelling now subsided, the pain ceased, and the patient fell asleep.

5th.—As the swelling and pain had again increased, I removed the plugs, and discharged a small quantity of pus, which was but slightly tinged with

blood. From this period the discharge of matter gradually ceased: the gum healed, and gave me no more trouble. At the end of three weeks the incision in the neck was nearly healed: but the ligature was undetached. My patient was now allowed to leave his bed, and was put on full diet. The case proceeded so satisfactorily from this time, that I lost sight of it until December 25th, when my patient reported himself as proceeding fast to recovery. The ligature had come away spontaneously, the neck was quite healed, and the swelling fast subsiding.

April 20th.—The patient is now healthy and well, the tumor entirely gone, the passage of the left nostril perfect, and he can open his mouth as widely as usual, but some deformity remains in consequence of the projection outwards of the malar bone. On examining the mouth, a distinct fissure can be felt on the palatine process of the palate and maxillary bones.

That this was a case of aneurism I have not the slightest doubt; but I am not quite certain as to the individual artery involved. From the history the patient gave of the tumor, I am inclined to think it was an aneurism of the internal maxillary, which commenced deeply, and posteriorly to the ramus of the jaw, extended downwards to the neck, and upwards behind the malar bone: causing a passage by absorption into the antrum, finding its way thence into the nose, and finally producing absorption of the floor of the nostril, it made its appearance under the mucous membrane of the palate.

IODINE IN PHTHISIS PULMONALIS.

To the Editor of the Medical Gazette.

SIR,

THE local application of iodine is of acknowledged use in healing external ulcers; therefore, by analogy, it is concluded to be of similar use in pulmonary abscesses communicating with the atmosphere: experience also corroborates the above conclusion.

Though physicians agree in the principle of action, yet they differ in the mode of application. Sir C. Scudamore recommends the inhaler; Dr. Corrigan impregnates the atmosphere of the patient's room with iodine.

Both methods being inconvenient in practice, I direct the patient to apply a sufficient quantity of iodine ointment on the ribs, under both axillæ, and to cover the head with the bed-clothes, to breathe the iodine volatilized by the heat of the axillæ; the ointment produces counter-irritation on the skin where it is applied, and is to be repeated according to circumstances. This method has appeared to me to arrest the progress of the disease; and as I should wish to hear the result of more extensive trial, I beg you will place the above remarks (if you think them worth inserting) in the *MEDICAL GAZETTE*.—I remain, sir,

Your obedient servant,

ALEXANDER LEIGH,
A.B. M.B.

3, Olympic Place, Jersey,

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Handbuch der Geschichte der Europäischen Medicin, Chirurgie, Pharmacie und Naturkunde in philosophisch practischer entwicklung Von HOFRATH Dr. ISENSEE, Universitätslehrer, practischen Arzte und Operateur in Berlin, &c. Berlin, 1839-41.

Hand book of the History of European Medicine, Surgery, Pharmacy, and Natural History, in their philosophico-practical development. By Dr. ISENSEE, Court-councillor, Teacher at the University, Practising Physician and Operating Surgeon at Berlin, &c. &c.

THIS is one of the most comprehensive, complete, learned, and at the same time succinct histories of the medical sciences with which we are acquainted. It satisfactorily fulfils the promise held out by its title, and considering the wide scope of the latter, this is no little praise. From the number of authors whom it notices, and from the care with which the titles of their works are quoted, it is invaluable as a book of reference. It gives a complete list of the writings of Aristotle, and also of those of Hippocrates, with brief critical remarks on each of the latter. We cannot better convey to our readers an idea of its merits, and of the system on which it

is arranged, than by following the author through a stage of one of the periods of the history of medicine. We will choose, for the sake of example, the "Roman epoch" (p. 103). This period is divided into three principal sections; the first treating of the progress of medicine in Rome before Galen; the second, of the same by means of Galen; and the third, of that which was effected after Galen. It is to the commencement of the first section that we must confine ourselves. The author first gives us a page of general reflections on the peculiar character of Roman intellect and mental cultivation. The next two pages are entitled, "A retrospective glance on medicine in Rome in its earliest ages" (with references to the ancient historians, and to Gans and Niebuhr amongst the moderns). Then follows a sketch of Asclepiades: 1. of the circumstances of his life; 2. of his writings; 3. his manners and style as a physician; 4. his medical system, viz. *a*, his therapeutics; *b*, materia medica; *c*, pathology; *d*, anatomy and physiology; *e*, general views. Finally, half a page is devoted to the enumeration of his scholars. The whole sketch of Asclepiades and his school occupies seven pages, and displays the most careful research, and also mature judgment.

Two parts of this work have already been published: the second and larger one brings down the history of medicine to the seventeenth century.

The Surgical Anatomy of Inguinal Hernio, the Testis, and its Coverings. By THOMAS MORTON, one of the Demonstrators in University College, London; and formerly House Surgeon to the Hospital of the same College. Illustrated with lithographic plates and wood engravings. 8vo. Taylor and Walton.

WE had much pleasure, some time since, in expressing a very favourable opinion of Mr. Morton's work on the Perinæum, the first of a series which will embrace all the most important regions of the body. The subjects discussed in the present volume are treated of in the same clear and useful style which was the great recommendation of the former. The engravings are well executed, from admirable drawings,

and the work altogether is one of those which, without the pretence of originality, where novelty is nothing, has the great merit of being eminently practical where practice is every thing.

MEDICAL GAZETTE.

Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."
CICERO.

THE ANATOMY BILL.

A CONVERSATION took place in the House of Commons last week respecting the working of this measure. Mr. Maclean and Mr. Duncombe gave an account of the "great dissatisfaction" which prevailed as to the manner in which the Bill has been carried out. Now had they stated the grievances at this time last year, the necessity of some change or of some energetic inquiry, would, we believe, have been generally admitted; but it must be confessed that during the season just past the Anatomy Bill has been acted upon in such a manner as to have produced a very satisfactory result. This at least has been the case in London, and, as far as we have been able to learn, the management for the provincial schools has been equally good; and we state this with the more pleasure, from the belief that the regularity with which, whenever they were growing lax, we stimulated the energies of those on whom the working of the Bill mainly depended, has contributed in no small degree to bring about this full accomplishment of the purposes of the Act.

The exertions made by the London Inspector during the past season have been, we are bound to say, very creditable; and the only reason why we, who have always so readily told him

his faults, have not sooner accorded to him this praise, has been that we feared he might think energy enough had been employed, and might too soon again retire to that life of ease and calm repose, which he seemed at first to regard as quite compatible with the duties of a somewhat laborious office. But we do hope that now, when he has seen how much may be effected by exertion, and how amply the powers under his control are sufficient to accomplish all that the anatomical schools can reasonably expect, he will not henceforth relax in his endeavours, but will obtain each year, as he has during the past, a supply that shall be even something greater than the demand.

The abundance of subjects during the past year has been chiefly drawn, we believe, from the metropolitan workhouses, from several of which the body that would formerly have been buried at the parish expense have been sent to the anatomical schools. One reason of this has undoubtedly been the withdrawal of Mr. Roberts, the gentleman who, being the inventor of a system for preserving bodies from decomposition, was naturally anxious to embarrass, as far as possible, the scheme by which a sufficient supply of fresh subjects could be obtained, and who therefore annually got up an excitement by hand-bills and placards, in the neighbourhood of the chief workhouses, to lead the poor to feel horror at the very name of an anatomical school. We long ago exposed the absurdity of attempting to apply any of the modes of preservation yet discovered to the subjects for dissection. We feel assured that neither Mr. Roberts's, nor M. Gannal's, nor any other yet invented, can be advantageously adopted for this purpose; and we now are happy to believe that the only circumstance that could render them worthy of consideration, namely, a de-

ficient supply of subjects in the recent state, is removed.

But we believe that a cause yet more efficient than this, in securing the full supply, has been the rational indifference with which the dissection of bodies, when decently performed under authorized superintendence, is generally regarded. There is really no public feeling whatever upon the subject now; and men of sense being left to the right exercise of their judgment upon it, unmoved by prejudice or the clamour of ignorance, of course decide in the manner most favourable to the anatomical schools. Much of this has depended on the repeal of that enactment which consigned murderers' bodies to dissection, and so conferred on all who shared the same fate a portion of their dishonour. But much more has resulted from the quietude in which the bill has been allowed to work. We fully accord with those members of the House who deprecated the public introduction and discussion of the subject, for the purpose of any slight alterations that might be made; it is peculiarly one of those measures in which a full discretionary power should be allowed to authorities, for the purpose of introducing, from time to time, such modifications as, without affecting its general principle, may adapt it to changing circumstances, and to cases the occurrence of which was not, and perhaps could not be, calculated on. Perhaps there is no measure of recent years in which, at its first enactment, so much of the detail was undetermined, and left to be filled up at discretion by the Home Secretary of State; in fact, the whole working of the bill has been the subject of arrangements made subsequently to its being passed; and the result of thus keeping the subject from being perpetually brought under public notice has been most beneficial; for

the evils of occasional delay and frequent inactivity have been more than counterbalanced by the absence of excitement, and its necessary consequent, public prejudice.

As an instance in proof of this, we will mention but one important addition made to the bill during the last season. Under the original enactment there was nothing to provide for or against the dissection of still-born children; and these were therefore commonly brought to anatomical schools by nurses, or at last even by men who made a sort of trade of them, and there left without further inquiry. Such a plan was probably harmless, but it admitted of abuse; and last year a case happened in which there was some suspicion (which, however, we believe was subsequently proved to have been unfounded) that a child murdered by its mother had been disposed of at an anatomical school. The immediate consequence was an order from the Secretary of State, that in future no fœtus should be received at a school without sending to the inspector a certificate of its birth, and its death before or directly after birth, signed by the medical attendant, or some other person present at the time, and by the teacher receiving the body. The result has been, indeed, that the number of fœtus brought to the schools has been greatly diminished, the parents not liking such facts to be generally known; but this will probably be but a temporary evil, and even if it continue it will yet be far better than the great amount of injury that would have been done had the public been excited by the same arrangement being made the subject of parliamentary legislation.

On such a subject, and on all of the like kind, when they are prominently brought before them, even the higher classes of the laity are scarcely capable of forming a calm and correct judg-

ment; and there is little doubt that the mode in which dissections are carried on, even with the most perfect observance that is possible of all decency, would appear to them very disgusting, and perhaps deserving of legislative interference for its improvement. The wisest course that they can pursue in such matters is to turn their thoughts away from them; just as, in their ordinary walk through the world, they turn away their eyes from any object that is offensive, but if they believe that it performs some useful office, or is essential to their own or others' comfort, leave it unmolested in its offensiveness. Dissecting and dissecting-rooms are signally useful objects of disgust; they are sometimes loathsome even to those who are most familiar with them, and most obliged to keep down their aversion; but in this respect they are not capable of much improvement, and the public, who at last reap the greatest benefits from them, must be content to leave their management in the hands of those who can alone judge dispassionately where, in such cases, necessary indifference ends, and where indecency begins, and on whom they can, in some measure, rely that the limit will not be overpassed.

We sincerely hope, therefore, that Mr. Maclean will, when he has read the report, be induced to think it satisfactory, and bring forward no measure founded upon it. The only subjects of any general importance to which it will relate, are the contraventions of the Act by teachers or students since its enactment, and the proceedings, if any, which have been taken thereon. We can ourselves, we believe, give the answer; which is, that the contraventions (at least such as on a liberal interpretation of the bill can be so called) have been very few and unimportant; and that the proceedings upon them have not amounted to more than re-

proofs from the inspector, and threats of punishment more heavy if the offence were repeated. But, really, neither this nor any of the questions that will be answered in the returns, would at all merit the trouble of legislation, even if it could be carried on without evil. The errors in the working of the Bill are not, or rather were not, such as Acts of Parliament can remedy; the want of energy in its management has been found curable by an occasional sharp stimulus; and it is to be hoped that, this being effected, there will henceforth be no great cause for complaint.

With respect to the distribution of the subjects, which was introduced into the conversation, and which is another arrangement added to the Bill by the consent of the Home-office, to whom it was recommended by the inspector (we believe, at the request of the majority of the anatomical teachers); this, if it has been carried out fairly, (and we know of no facts to prove the contrary) is in nowise objectionable, so long as the supply of subjects is not suffered to fall below the demand for them. When the number obtained by the inspector is deficient, through his lack of zeal or of influence, an equal distribution is mischievous, because, as we have very often said when the question has been under discussion, there is no inducement for the more influential among the anatomical teachers to use any exertion to obtain subjects, which will probably be taken, not to their own schools, but to those of their opponents. And in past years this has commonly happened; the inspector, taking the office of distributor, has of necessity become purveyor also, and, unless he discharged thoroughly well the duties of this last office, the power which he exerted in the second was very mischievous, and the first would soon have become a sinecure.

But the case is different when there are plenty of subjects in the common stock to distribute; then an equal partition of them is as much the most convenient as it is obviously the fairest method. Indeed, in such a case the chief purpose which the system accomplishes is not so much the preventing one school from obtaining an excess while another has a deficiency (for none would necessarily incur the annoyance and expense of an excess), as the distributing the subjects to all the schools equally, so that none of them may be at one time burdened, and at another empty. During nearly the whole season just past this purpose has been well and steadily attained; at the very beginning there was some deficiency, and at Christmas (when the number of pupils was diminished by the fortnight's vacation) there was some, and even a considerable excess; but, on the whole, there was such a supply that most of the teachers may congratulate themselves if the Bill be as well worked in all future years. And all this we may add was effected in a season during which the amount of illness among that class of the poor from whom the dissecting rooms are chiefly supplied was less than the average; for we had neither severe influenza nor fever, nor any other destructive disease in an epidemic form. We repeat, therefore, our sincere hope that the Bill will be left undisturbed: so long as energy is employed in working, it is amply sufficient for its purpose.

DEATH OF DR. HOPE*.

WE regret to announce the decease of Dr. Hope, which took place at Hampstead, on the 13th instant.

Dr. Hope was in the 41st year of his age, and the complaint which proved fatal was pulmonary consumption. He was the author

* This notice was accidentally omitted last week.

of a work on the heart, which has attracted a large share of attention; he also published a set of plates illustrative of morbid changes of structure in the human body. Some years ago he held the office of Physician to the St. Marylebone Infirmary, and afterwards became one of the Physicians to St. George's Hospital.

DEATH OF THOMAS HODSON, ESQ.,
SURGEON AT LEWES, IN
SUSSEX.

(From a Correspondent.)

THE subject of this memoir was the son of the Rev. Henry Hodson, Rector of Sandhurst, Kent. He prosecuted his medical studies at the hospitals of Guy's and St. Thomas's, London, where he had for one of his teachers Mr. Cline, and as a contemporary the late Sir Astley Cooper, with both of whom he maintained a friendly intercourse till they died.

Mr. H. received an honorary certificate of proficiency in his studies from his medical school, and commenced his practice, as a general practitioner, at Lewes, in Sussex, in 1786. Soon after he became a member of the College of Surgeons of London.

He early distinguished himself by the operation of lithotomy, which during the course of his practice he performed upwards of forty times with the loss only of three patients—a degree of success scarcely surpassed by that of the most eminent surgeons of the metropolis. The zeal which he shewed, and the knowledge which he possessed of his profession, and the liberal and kind manner in which he practised it, are well known to the physicians and surgeons of Lewes and its neighbourhood, as well as to many of the most eminent surgeons of London, with whom he had frequent intercourse and consultations.

About twenty years before his death he formed the plan of transferring his residence to Brighton, where the frequent resort of the Court, and the prospect of a county hospital (soon after established there) seemed to offer a more extensive field of practice; but this project he never carried into effect, though he often regretted he had not. He closed an active and useful life, April 13th, 1841, in the seventy-ninth year of his age*.

Of three sons and a daughter, the last only survived him, now married to the Rev.

Edward Bull, Rector of Pentlow, Essex. Mr. Hodson was a man of great integrity and simplicity of character, retaining a taste even to his later years for the manly exercise of his youth, hunting, shooting, and cricket—amusements in which professional business rarely permitted him to indulge.

For several years of his life he expressed to some friends doubts on religious subjects; but there is reason to believe that in his later years these doubts were removed, and that he died in the faith and hope of a Christian.

CLIMATE OF TEXAS.

To the swarms of medical practitioners that yearly issue from the universities and colleges of Europe, Texas offers little encouragement as a field of professional speculation. There is no malady that can be properly called endemic; and the febrile diseases which usually afflict early settlers, especially in southern latitudes, are of a mild type, completely within the control of medicine, and generally to be avoided by the observance of a few simple rules of living. Emigrants accustomed to northern habits, should, at least until they are thoroughly "acclimated," shun undue exposure to the noonday sun; exercise caution in the use of fruit and salted food, abstain from ardent spirits, and refrain as much as possible from drinking, save at meals. To persons new to the climate, occasional cathartics, followed by the use of bark, are beneficial. Very frequently, the injurious effects attributed to climate are caused by intemperance, or the neglect of some of those precautions of which the climate of every latitude demands its peculiar share. If any part of Texas can be termed sickly, it is the narrow strip of country running parallel to the gulf, where in the low timbered bottoms the rivers deposit the accumulations of their annual overflows. In this section, to which Providence has granted exuberant fertility, in compensation of its comparative insalubrity, settlers are liable to be attacked by bilious and intermittent fevers; but after receding some distance from the coast, no part of the globe is more friendly to the regular action of the human frame. The towns immediately on the coast, within the direct range of the trade winds, are healthy, although rather trying to temporary sojourners from cold climes, during the months of June, July, and August. Pulmonary consumption, so destructive in England and the Northern States of the American Union, is almost unknown in Texas. Rheumatisms and chronic diseases are not prevalent; and nine-tenths of the Republic are considered healthier than the most healthy parts of the United States. In the opinion of respecta-

* The disorder of which Mr. Hodson died was apoplexy. The first threatening of it took place about three weeks before his death, by a sudden involuntary dropping of his left arm. This was very transient, the usual power and feeling returning immediately. It occurred on six or eight different days. On the 10th of April there was slight distortion of the mouth; on the 12th hemiplegia of the left side; and on the 13th he died.

ble medical men, a residence in this country would be as favourable to persons of a consumptive tendency as the south of Europe, or Madeira. As a general fact, it may be stated that the farther from the lands bordering on the coast, the more salubrious is the locality; and persons who arrive in summer will be quite safe by retiring fifty or sixty miles inland. Western Texas is best adapted to a nothern constitution; and above the falls of the Brazos, or in the region lying about seventy miles above the mouths of the rivers westward of the Brazos, natives of Great Britain may settle with at least as fair a prospect of longevity as they had at home." — *Kennedy's Rise, Progress, and Prospects of Texas.*

Winds variable, S.W. prevailing.

On the 19th, overcast, raining frequently during the day; wind boisterous. The 20th, generally clear, rain at times. The 21st, evening overcast, with rain; otherwise clear. The 22d, cloudy, rain fell in the afternoon. The 23d, and following day, clear; vivid lightning in N.E. from about 10 p.m. till after midnight of the 24th. The 25th, evening overcast, otherwise clear; lightning during the evening.

Rain fallen, .365 of an inch.

CHARLES HENRY ADAMS.

UNIVERSITY OF LONDON.

On Wednesday last the Senate of the University of London passed a resolution to the effect that all students who commenced their medical studies, either as apprentices, or in any other way, in or before January 1839, will be exempted from the Matriculation Examination, whenever they may present themselves for the examination for bachelor of medicine.

LECTURES AT THE COLLEGE OF SURGEONS.

THE Surgical Lectures for the present season are to be delivered by Mr. Guthrie; and the subjects he has chosen are Injuries of the Head, Chest, and Abdomen. They commence Tuesday June 1st, at 4 o'clock p.m.

DR. CARPENTER'S AND DR. CORRIGAN'S LECTURES.

Dr. Carpenter's Lectures will be resumed in the next number but one, and afterwards continued without farther interruption.

Dr. Corrigan's Clinical Lectures will also be resumed in an early number.

NOTICES.

We should not feel justified in giving up so much of our space as Mr. M.'s (of Leeds) would occupy; but if he can state the circumstances within a page, we shall publish them for him.

The discussions contained in the letters of Mr. F., of Liverpool, and Mr. C., of Glasgow, can only be continued in the *extra limites* department.

M.R.C.S. — The party is entitled to charge for his visits; but we cannot speak as to the amount without knowing more of the circumstances.

WILSON & OGILVY, 57, Skinner Street, London.

LECTURES
ON THE
PRINCIPLES AND PRACTICE OF
PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

LECTURE XXXVII.

Chorea. Symptoms; pathology; complications; causes; treatment. Chronic Chorea. Other Nervous Disorders to which the same name has been applied.

Chorea.—Another disease of a spasmodic kind, and essentially belonging to the nervous system, is *Chorea*—*St. Vitus' dance*. This is far less serious than the complaints which we have recently been considering; but it is a very unpleasant disorder to suffer, and it has several points of analogy with the other nervous and spasmodic ailments. Its prominent symptom is an irregular and involuntary clonic contraction of some of the voluntary muscles, which, however, are not wholly or constantly withdrawn from the government of the will. In tetanus we had rigid spasm, while the mind was clear and free; volition was unaffected, but the muscles which should have obeyed the effort of the will were seized upon by some stronger overruling power. In epilepsy, with convulsive spasm, there was suspension of the mental functions; a temporary interruption of consciousness, and therefore of volition. But in chorea we have a different state from either of these: there is no loss of consciousness; no defect of volition; the ordinary movements of the body can be performed in some degree, or sometimes, under the direction of the will; but it would seem as if some other power wantonly interfered to excite them when they are not needed, to

render them unsteady and imperfect, to arrest the natural action, and give a new direction to the limbs, and to cause the patient to gesticulate and grimace like a Merry-Andrew. Moreover, these apparently absurd movements do not occur in paroxysms, but continue throughout the day, sometimes for weeks together; but they generally cease during sleep: for the most part, but not always, the agitated limbs are still, while the senses are shut up in slumber. The complaint is not attended with fever.

Symptoms.—This disorder was first distinctly described by Sydenham, whose account of it is very graphic and excellent, and has been copied by most subsequent writers. Without reference, however, to the portrait which he has left us, I will sketch the disease as it has occurred under my own observation. It usually begins with slight twitches of a few muscles in the face, or one of the extremities; and by degrees the spasmodic action becomes more decided and more general. All the voluntary muscles are liable to be affected by it. Those of the face seldom escape. The features are twisted into all sorts of ridiculous forms; you might suppose that the patient was what is called pulling a face, or making mouths at you; but there is neither mirth nor mockery in the contortion; it is a convulsion: it is succeeded by a vacant look, and then it begins afresh. The disease occurs much oftener in young girls than in any other persons. If you ask the patient to put out her tongue, she makes sundry attempts to do so before she can accomplish it; and then the tongue is suddenly thrust out, and as suddenly withdrawn, and the jaws snap together as if she were resolved that you should have as short a glimpse of it as possible. She writhes and contorts her shoulders; she cannot keep her hand or arm half a minute in the same position; when, at meals, she desires to carry her hand to her

mouth; it is arrested midway, and suddenly pulled back again, or pushed out in some other direction; and it is only after many deviations and fruitless efforts that she succeeds. The lower extremities are equally affected: when the patient intends to sit or stand still, her feet scrape and shuffle on the floor, or one is thrown over the other; and if she endeavours to walk, her progress is most uncertain; she halts, and drags her leg rather than lifts it up, and advances in a jumping manner, and by fits and starts. In short, the voluntary muscles are moved in that capricious and fantastic way in which we might fancy they would be moved if some invisible mischievous being, some Puck or Robin Goodfellow, were behind the patient, and prompted the discordant gestures. With all this the articulation is impeded; there is the same perverse interference with some of the muscles concerned in the utterance of the voice. By a strong figure of speech, the disorder has been called "insanity of the muscles."

Such is a picture of the main symptoms of this strange malady, as they have presented themselves to me; and such, I venture to say, you will often see in your future practice. You will find, moreover, that the irregular jactitations are usually more marked and general on one side of the body than on the other; and sometimes they are confined to the muscles of one side. Here, therefore, we have a trait of resemblance to epilepsy and to hemiplegia. If you take hold of the only limb which happens to be thus agitated, and keep it still by main force, some other limb or part will take on the convulsive action. The persons who are subject to chorea are always inordinately sensitive, and what is popularly called "nervous." They are easily moved by new ideas and sudden feelings, and pass readily, and upon slight occasion, from one mood of mind to another. The mind is affected, as Dr. Cullen remarks, in the same way, and often shews the same varied, desultory, and causeless emotions, as in hysteria. You see the indication of this nervousness in the fact that the fidgetty catching of the muscles increases when the patient is spoken to, especially by a stranger—by the physician, for example. The nurses of the hospital constantly tell me that such and such a patient, who has chorea, is much more composed at other times than she is during my visit, when she is surrounded by students, and made the object of their attention. In most cases the jactitations are partly and in some degree under the influence of the will: sometimes the patient seems to give way to them, indulges in or exaggerates them; at other times she can, by making an effort, control them. Many of the patients, espe-

cially such as are old and intelligent enough to understand the directions given them, and to make the trial fairly, can suspend for some seconds the convulsive movements, by taking a deep inspiration, and resting upon it, without expiring, for a little while. Like other spasmodic diseases occurring in moveable constitutions, chorea is liable to be propagated also by a species of contagion, or rather of involuntary imitation. These diseases constantly approximate and touch each other in some of their characters.

Chorea, in this its standard form, is essentially a disease of youth. Sydenham, and Cullen who closely copies him, state that for the most part it attacks boys and girls who have not reached the period of puberty; between the tenth and fourteenth years of their age. These limits are, however, too scanty. It is very common between the eighth and sixteenth years; it sometimes comes on as early as five or six; and now and then it begins in adult life, or in old age. I have already intimated that it is much more frequent in girls than in boys. Dr. Heberden says the proportion is as 3 to 1. Dr. Elliotson, out of 30 patients, had 22 females and 8 males. Of 84 cases reported by Dr. Reeves, of Norwich, 57 were females, and 27 males. Of 72 occurring in Dr. Manson's practice at Nottingham, 53 were females, 19 males. Of 18 cases in the Hampshire County Hospital, 12 were girls, and the rest boys. Now taking all these numbers together, we have 204 cases, of which there were 144 females and 60 males; the proportion is as 12 : 5, or a little more than 2 : 1; and leaving out Dr. Reeves' list—which differs considerably from the others in containing a larger number of males—we have 120 cases, of which 87 were females, and 33 males: this ratio is as 29 : 11, or nearly, but not quite, 3 : 1. I have also observed that the disease occurs much more frequently in children having dark hair and eyes, than in those of a light complexion; and I think I have seen the same remark in some author, but I forget where.

When the disease is strongly marked, or lasts long, there is usually some imbecility of mind manifested; a slight degree of fatuity, and a foolish expression of the features. But this goes off with the other symptoms. The child generally recovers, but the disease is apt to recur, and that more than once. In this respect we may trace a distant resemblance to epilepsy: if we regard each attack as a long and mild paroxysm, then these paroxysms are liable to repetition. No doubt the duration of the disorder is often abbreviated by proper treatment: there are *cures* in this disease as well as *recoveries*. It is a very rare thing for

chorea to prove fatal; and the few fatal cases that have occurred have thrown no light on its pathology. Dr. Elliotson saw a strong girl affected with it die of apoplexy; but perhaps she would have died of apoplexy whether she had had chorea or no. Chorea offers no protection against the invasion of other diseases. My colleague at the Middlesex Hospital, Dr. Hawkins, had a fatal case. He found great vascularity of the uterus, earthy concretions in the pancreas, omentum, and mesentery, and tubercles in the lungs. But these appearances had no connexion probably with the chorea. In an instance that proved fatal under Dr. Bright's observation, there was considerable disease in the uterus and its appendages. I am afraid that we shall seek in vain in the dead body to discern the *nature* of chorea. When we find organic disease accompanying it, we must look upon such organic disease, if it have any connexion with the chorea at all, as being a predisposing cause; as producing or increasing that irritability and mobility of the nervous system which fits it for submitting to the exciting causes of various nervous diseases.

Pathology.—There is a speculation of some of the French writers respecting the seat and nature of chorea so ingenious, that I cannot refrain from mentioning it.

It is affirmed by certain modern physiologists, as you may perhaps know, that one of the functions, the principal office indeed, of the *cerebellum*, is to preside over and regulate the faculty of locomotion; to keep the muscles in due subordination, as it were, to the will. No voluntary movement, almost, can be executed without the combined and consenting action of many muscles: it is the business of the cerebellum, they say, to maintain this consent and community of purpose; to prevent any mutiny of individual muscles, and to make them unanimously co-operate in producing a given movement. How far this doctrine is true I do not intend to enquire; but, supposing it well founded, then they very ingeniously assign the cerebellum as the seat of that change, whatever it is, which gives rise to the phenomena of chorea. And it is most certain that the irregular movements by which chorea is characterized can neither be considered as the effects of imperfect paralysis, as some have stated, nor of convulsion, in the proper sense of that word, as others have asserted; but rather as consequences of the want of due harmony and agreement between the various muscles, which should combine to produce the desired state either of rest or of motion. There is a defect of the requisite association in the action of the different muscles; and it is in this sense that chorea has been denominated *insanity* of the muscles. There is a certain

portion of the brain which ministers to the intellectual functions; there are certain altered states of that portion, which lead to mental aberration; the persons so affected form false judgments, cannot associate their ideas aright. So also there is a certain portion of the *encephalon* which presides over the locomotive functions; and there are altered states of *that* portion, which lead to a loss of the due association of the muscular contractions. That portion is the *cerebellum*. Such is their theory: and it is a very plausible and pleasant, but withal an unsatisfying theory. The disorder really belongs, I apprehend, to the *excito-motory* division of the nervous system. From some unhealthy or unnatural state, either of the cord or of the incident nerves that convey impressions to it, its reflex function is called into irregular play, and voluntary muscles contract independently of volition. Sometimes at the same instant the patient *wills* certain definite movements through the instrumentality of the very same muscles. The consequence is, that the same muscles, receiving at the same time contradictory orders from these two sources, obey neither mandate completely, but give rise, by their discordant action, to the grotesque and seemingly antic gestures which these patients exhibit.

But to leave these seductive theories, and to return to duller matters of fact. Chorea is a complaint that is seldom attended with any bodily pain. I have in several instances, however, known it to be accompanied by pain of the head; and in some of them, with pain on that side *only* of the head which was opposite to the agitated limbs. I mention this as being of some practical importance; for I have found the disease to become sensibly less severe, and very soon to cease, upon drawing blood by leeches, or cupping, from the painful side of the head. In a greater number of cases, however, no such pain is experienced. Sometimes you will find that in all respects, excepting the nervousness, and the irregular movements, the patient is in the enjoyment of perfect health. But neither is this very common: generally there is something manifestly wrong in the state of the stomach and bowels, either before or during the complaint; a capricious appetite, costiveness, a tumid abdomen, offensive breath, a foul tongue.

Complications.—Chorea is sometimes complicated with other disorders, and above all with hysteria; and no wonder, since they both occur chiefly in persons of the same sex, of the same temperament, and at nearly the same period of life. It is said also to happen in conjunction with acute rheumatism and rheumatic pericarditis; and with certain affections of the skin. Its coincidence with cutaneous complaints I sus-

pect to be accidental; and I should not say, judging from my own experience alone, that the disease was often associated with acute rheumatism. Dr. Copland and Dr. Bright have both, however, noted that connexion, and therefore I cannot doubt that it does sometimes exist. I certainly have seen jactitations like those of chorea in a few instances of rheumatic carditis. Very lately a boy, affected with chorea, became my patient in the hospital. We soon detected a strong bellows-sound of his heart; and tracing his history back a little, we found that he had suffered acute articular rheumatism. In a recent volume of the *Medico-Chirurgical Transactions*, there is a paper by Dr. Bright, detailing "cases of spasmodic disease accompanying affections of the pericardium." Now we do not perceive any obvious or direct connexion between the cardiac disorder and the nervous disorder. There are just two conjectures which occur to me upon the subject. Rheumatism (as we shall see by and by) is especially a disease of fibrous structures, and it usually affects various fibrous parts at the same time. It is not improbable therefore, that, in the cases in question, some morbid condition of the membranes of the spinal canal may have arisen, simultaneously with the inflammation of the pericardium; or the cardiac disease may perhaps operate, by some ill-understood influence, upon afferent nerves of the cord, as an eccentric cause of the irregular movements.

Causes.—Probably any thing which makes a strong impression on the nervous system may act as an exciting cause of chorea. Strong mental emotion, or a sudden mental shock, is very likely to bring it on in those of a moveable constitution who are predisposed to it. Of its ascertained or alleged exciting causes, *fright* is beyond all comparison the commonest. It has been known to follow a blow or fall on the head; but even in these cases the alarm may have had more to do with the disorder than the blow itself. It sometimes seems to depend upon irritation of the stomach or bowels, by improper diet, by accumulated feces, or by worms; and it is found to be connected, in not a few cases, with difficult and painful menstruation. It frequently begins about the period of the second dentition: the late Dr. Gregory, of Edinburgh, was in the habit of relating instances of that kind. In one case, the old teeth were remaining while the new ones were appearing by their sides. The old teeth were drawn, and the removal of the chorea was complete. This Dr. M. Hall would justly call eccentric chorea. But even in such cases the state of the gums cannot be regarded as the sole cause of the chorea: there must be the predisposition, as well as the accidental exciting cause; for the com-

plaint is apt to recur under the agency of some new irritation, and may then be removed by other means.

Chorea, such as I have been describing it, may last from a week or two to some months. In those eighty-four cases which I have already mentioned as having been reported by Dr. Reeves, the shortest period of medical treatment was two weeks; the longest eight months; and the common average seven weeks. This appears to me a long average. The disorder often terminates—at any rate much more often than epilepsy does—at the period of puberty; especially upon the first coming on of the menstrual discharge in the female.

I had occasion, in the last lecture, to remark, that when a vast number of different drugs are recommended as specifics in any given disease, we may sometimes infer from that very circumstance that the disease is difficult of cure, and generally intractable under all plans of management. But there is another class of diseases which a variety of drugs are supposed capable of curing,—those, namely, which tend to terminate in health. I believe that many cases of chorea—most cases—would at length get well without any aid from physic: I believe also that many of the boasted specifics have been quite innocent of any share in the recovery of the patients to whom they were administered; at the same time I am quite certain that treatment has a great influence over the disease.

Treatment.—It was Sydenham's practice first to bleed and purge his patients, and then to administer bitters, aromatics, and antispasmodics, with the object of strengthening the nerves. After his time the blood-letting and purgatives fell into disuse, until the publication of Dr. Hamilton's well-known work brought the latter deservedly into favour again.

A main part, however, of the treatment, consists in the employment of such measures as are calculated to give stability to the moveable nervous system. I can confidently recommend you to abstract blood locally in those cases in which there is a fixed pain in the head; but with this exception, blood-letting is neither useful nor even, in my opinion, justifiable.

I shall not attempt to distract your attention by discussing the various remedies that have been vaunted against chorea; but shall take the liberty of referring you to books (to Dr. Copland's *Dictionary*, for example) for farther information on that subject, and content myself with telling you what modes of treatment I have been in the habit of employing, with very satisfactory results. I think, then, that, setting aside the complication with headache just mentioned, you will be able to deal successfully with most of

the cases of chorea which you may have to treat, if you have at your command purgative medicines, the shower bath, preparations of iron and of arsenic, and oil of turpentine.

It will be right, in all cases, to begin by clearing out the bowels by calomel and jalap, or some active aperient; and you should persist in the regulated use of purgative medicines, if they continue to bring away much fecal matter. We are to be guided less by the amount of the doses than by the effects they produce; at any rate one full evacuation of the bowels should take place every day. But though purgatives are good auxiliaries, we cannot trust to them alone for the cure of the complaint.

One of the most effectual of the tonic remedies is the cold shower bath. If the patient be of a feeble constitution, the water may at first be used tepid; by degrees it should be used cold. This remedy should be employed every morning, or every other morning, early, as soon as the patient gets out of bed. Of the best indications of the propriety of its continuance I spoke in the last lecture only; I need not tire you, therefore, by repeating the observations I then made.

With this external tonic it will be right to combine some internal one; and for the most part the best for the purpose is some preparation of iron. The carbonate of iron is an exceedingly good form, and it may be given in the way recommended by Dr. Elliotson, one of whose *pets* it is,—namely, mixed with twice its weight of treacle, so as to form an electuary. You may begin with it in half-drachm doses, and presently increase the quantity to a drachm, or a drachm and a half, or two drachms. Much larger quantities than this have been given, and that for a long time together; but I am not in the habit of so pushing this drug. Patients do not like to swallow from half an ounce to an ounce of the powder and twice as much treacle three or four times a day; and some of them cannot get so much down. And I mentioned on a former occasion that the iron is apt to accumulate in the large intestines, and to be expelled at last, often with difficulty and pain, in large, hard, red masses, like what is called, I fancy, slag, or the dross of iron ore from a furnace. When one or at most two drachms given three or four times a day make no impression on the disease, you had better (in my humble judgment) change the form of the medicine. Give a grain or two of the sulphate of iron for a dose, or frequent draughts of Griffith's mixture (*mistura ferri composita*), or twenty or thirty minims of the tinctura ferri muriatis. Dr. Bright says he has found the sulphate of zinc answer when

the carbonate of iron had failed, and the iron succeed when the zinc had done no good. One most severe case, about which I was consulted, and which had resisted other remedies, got well under the use of the sulphate of zinc: the dose of which was gradually increased to ten grains, given three times a day. Whenever the medicine was pushed beyond this point it became emetic. Certainly the disease is often very obedient to arsenic; but, for plain reasons, it is better to effect a cure, when we can, by less hazardous substances. The severest case I ever had to treat occurred, not long since, in one of my hospital patients. I tried the carbonate of iron in vain. The shower bath so terrified and agitated the girl that I could not persist with it. I then gave her arsenic, under which she improved at first, but it ultimately was very injurious: her bowels were greatly irritated by it, she became paralytic in her lower extremities, and sunk into a typhoid state: and I really was afraid that I should lose her. But she recovered from this condition, which I could not but ascribe to the arsenic; and as soon as I dared venture, I began to give her the muriated tincture of iron, twenty drops at a time, every six hours. Under this treatment she steadily and rapidly improved, and was soon quite well.

The oil of turpentine also is certainly a valuable medicine in this disease: whether there be worms at the bottom of it or not. When the bowels are torpid, and the girl is of that age that menstruation may be conjectured to be at hand, its arrival seems sometimes to be accelerated, and great relief to be produced, by the turpentine. The best way of exhibiting it in such cases is in combination with an equal quantity of castor oil: two drachms or half an ounce of the *mixture* may be given every morning, or every other morning, according to its effect upon the bowels: and when they are very sluggish, or the stools are unnatural, it will often be serviceable to give a couple of grains of calomel also, twice or thrice a week, at bedtime.

It is scarcely necessary for me to say that in all cases due attention must be paid to the diet. This ought to be plain and simple, but at the same time nourishing, or even generous. And exercise, short of that which produces fatigue, in the open air, in fine and dry weather, will greatly conduce to the patient's recovery.

Chronic chorea.—There is an affection (it scarcely deserves to be spoken of as a disease) which is sometimes called chorea, or a chronic nature, and resembling the disorder I have just been speaking of inasmuch as it commonly is met with in nervous persons,

and consists in the irregular, unmeaning, and involuntary contraction of certain muscles, especially of the limbs, neck, or face: but differing from it in this—that the same muscles are always affected, and in the same way; that it lasts long, almost always for life, and implies no accompanying derangement of the general health. In its slighter form the irregular movements are rather *awkward tricks* than spasms: a repeated shake of the head, or knitting of the eyebrows, or corrugation of the integuments of the nose, or shrugging of the shoulders—which the person seems scarcely conscious of. At other times, however, the motions are more extensive; a limb starts out, or the head is turned awry; and the individual who performs these evolutions is quite aware that he does so, and vexed and annoyed at the ridiculous figure he makes, but he cannot help performing them; or if he can prevent it, the necessary effort is worse than the disease. One young man who was subject to this infirmity told a friend that he could stop the movement by a strong exertion of the will; but that *that exertion* was extremely painful, and was followed by languor and much discomfort. In some instances I make no doubt that the continuance of the affection is the result of a long-established *habit*. It occurs more frequently in men than in women. I had for a long time, as an out-patient at the hospital, a girl about seventeen years old, in all other respects the picture of health, but who was annoyed by an involuntary shake of the head, which took place two or three times in a minute. She received no benefit from medicine. A lad in my own service was affected in a similar manner. He seemed to be giving me, and my friends, from time to time, a familiar nod: and I was obliged to part with him. Others are subject to twitchings of the face. I am acquainted with one gentleman who is perpetually wrinkling his nose; and he has assured me that he was subject, when young, to an involuntary shake of the head, like the two persons just mentioned; but a blister having been once applied to his throat for some disorder in his air-passages, the shaking of the head was thereby rendered painful and difficult, and the movement there ceased: but (as he expressed it) it broke out in his nose, where it triumphs to this day. This *chronic chorea*, as it has been called, I merely mention to prevent your confounding together two affections which, though they have received the same name, and are in some respects analogous, yet differ in still more points, and those points of more importance. I believe that medicine has no power over any of these tricks. They are distressing and unsightly; but in no way dangerous.

The word *chorea*, which you know signifies a *dance*—and the trivial term of St. Vitus's *dance*—are not very appropriate to *either* of the modifications of the nervous affection which I have been noticing. In fact that term was originally applied, and much more suitably, to another set of symptoms of a most singular kind, concerning the real occurrence of which we might well be sceptical, if we had not authentic narratives of many instances of such disorder from different persons of credit, as well in this country as in others. What has happened, many times, before, may happen again; and you ought not to be in ignorance of the histories to which I allude. They relate to an affection characterized by movements that cannot be called spasmodic, but were rather owing to an irresistible propensity to muscular action, increased sometimes to a sort of mania by the force of imitation, or by the sound of music. It is the *volition* that, in these cases, is morbid and perverse. You might fancy the patient to be possessed and coerced by an evil spirit, like the *δαίμονιοι* of the Gospel history.

Some of the subjects of these extraordinary affections, impelled by a strange unintelligible necessity, execute measured and regular movements with surprising energy, rapidity, and perseverance. When music is performed in their hearing, the movements become an actual dance; and where crowds are collected together, the dancing mania is apt to spread from person to person by a sort of imitative infection; realizing the fable of Orpheus, and giving origin (it may be presumed) to those romantic legends, met with in the literature of most ages and countries, of universal, involuntary and unceasing saltation, at the sound of a magic pipe. To these feats the term *chorea* is apposite enough. Indeed I have seen it somewhere suggested that the phrase *chorea Sancti Viti* is but a vulgar corruption of *chorea Sancti inviti*; and took its rise in the misfortune of some holy person who chanced to be afflicted with one of these unwilling but invincible impulses to caper. The common explanation makes this holy person to have been a certain German Saint Weit, to whom a chapel is said (I know not with how much truth) to be dedicated at Ulm, in Suabia.

Sometimes, instead of dancing on their feet, these patients drum and beat with their hands, either upon their own knees, or upon the objects near them. This variety has received the bombastic title of “*malleation*.” Sometimes they circumvolve with great rapidity; or they turn their heads repeatedly from side to side with great velocity: this is “*rotation*.” When they are irresistibly impelled to move in a given direction, the term “*propulsion*” is employed. The very

invention of these names attests the reality of the disorder.

You will find one of these singular cases related by Mr. Kinder Wood, in the seventh volume of the *Medico-Chirurgical Transactions*.

The patient was a young married woman. After having suffered severe pain in one side of her face, she began to be troubled with involuntary movements. They commenced in the eyelids, which were opened and shut with excessive rapidity. Then the muscles of the extremities became affected. The palms of the hands were beat rapidly upon the thighs, and the feet upon the floor. The motions soon extended to the trunk and pelvis. The patient was suddenly half-raised from her chair, and instantly re-seated. This was repeated as quickly as one action could possibly succeed another. Sometimes she had a propensity to leap upwards, and strike the ceiling with the palm of her hand; or to touch little spots or holes in the furniture of the room. Or she would dance on one leg, holding the other in her hand. These attacks were accompanied by headache, sickness, and vomiting. At last she took to making steps about the room, regulated by an air, or by a series of strokes on the furniture as she passed: her lips moving as if words were articulated, but no sound escaping them. A person thinking he recognised the tune which she beat on the furniture, began to sing it; and she danced directly up to him, and continued dancing till he was out of breath. A drum and a fife were now procured, and the same air played upon them. She immediately danced up to the drum, and as close to it as possible, till she missed the step, when the motions instantly ceased; and this was found always to be the case. The motions stopped also when the measure was changed; or increased in rapidity beyond her power to keep pace with it. A continued roll on the drum had also the effect of putting an end to her movements. And this being discovered their approach was watched; and by always rolling the drum as soon as they threatened to begin, the chain of association which seemed to constitute the disease was at length broken. The bowels were in an unnatural state during the complaint; and the menstrual discharge appeared on the evening of the day on which it ceased. One might conceive that the conduct here described was an indication of folly or of insanity; but Mr. Wood declares that the patient's spirits were good, and her perception and judgment accurate and just: that during the absence of the paroxysms she went about her household affairs as usual; and that she had a correct knowledge of her situation, and of the advantage she derived from the drum, with an anxious desire to continue its use. She stated "that

there always was a tune dwelling upon her mind, which at times becoming more pressing, irresistibly compelled her to commence the involuntary motions."

In a lady, whom Dr. Abercrombie saw, the following symptoms, among others, occurred:—After she had been ill with various nervous affections for two years, she began to suffer convulsive action of the muscles of the back, and involuntary twitches of the legs and arms, producing a variety of movements of the whole body very difficult to describe. These were much increased by touching her, especially on any part of her back. This is a symptom quite in conformity with Dr. Hall's doctrine of eccentric irritation. At one time there was difficulty of deglutition, so that attempts to swallow produced spasms resembling those of tetanus. At other times, after lying a considerable time quiet, she would in an instant throw her whole body into a kind of convulsive spring, by which she was jerked entirely out of bed: and in the same manner, while sitting or lying on the floor, she would throw herself into bed, or would leap, as a fish might do, on the top of a wardrobe fully five feet high. These are feats that surpass the powers of a person in health: and I say we should hesitate to believe them if they were not related by a physician of such sober judgment and unquestionable veracity as Dr. Abercrombie. He tells us that during the whole of these symptoms her mind continued entire; and the only account she could give of her extravagance was, a secret impulse which she could not resist.

But after a time motions still more wonderful commenced, affecting the muscles of the upper part of the back and neck, and producing a constant semi-rotatory motion of the head. This sometimes continued without interruption night and day for several weeks together; and if the head or neck were touched, the motion was increased to a most extraordinary degree of rapidity. These paroxysms were relieved by nothing but cupping on the temples to the amount of ten or twelve ounces; when the affection ceased in an instant with a general convulsive start of the whole body. She was then immediately well, got up, and was able to walk about in good health for several weeks; when the same symptoms returned, and required a repetition of the same treatment. All this went on, at intervals, for four years; the menstruation during that time being irregular and scanty, and the bowels torpid. She was pale and bloodless from the frequent bleedings, but not reduced in flesh. At last, in the spring of 1829, she had a severe paroxysm of the rotatory motion of the head; and it was then determined to allow the attack to take its course, and to direct the treatment entirely to the menstruation.

Sulphate of iron, and Barbadoes aloes, were prescribed. She went on for three weeks, the convulsive motion of the head continuing without intermission night and day. At length, in the middle of the night, the paroxysm ceased in an instant, with the same kind of convulsive start of the whole body with which it used to cease after cupping. At the same instant menstruation took place in a more full and healthy manner than it had done for many years. From that time she remained well; at least up to the period when Dr. Abercrombie wrote the account.

This alternating rotatory motion of the head is by no means an uncommon feature of these singular cases. It occurred in a patient of Dr. Conolly's; in whom the menstruation was irregular, and about to cease altogether. It came on in paroxysms which were repeated many times a day, and was attended with inordinate loquacity. The head was turned from side to side about eight times in a second, and each paroxysm lasted three or four minutes. The patient got well after being cupped and leeches, and thoroughly purged. I have seen precisely the same thing in a hospital patient. Dr. Crawford met with an instance of involuntary rotation of the head, without pain, but attended with intolerance of light. And there is a striking example of it described in the twenty-third volume of the *Edinburgh Medical and Surgical Journal*, by Mr. Hunter, of Glasgow, who speaks of it under the name of "rotatio or chorea." The motions are said to have been furious and alarming: they were executed with such immense rapidity, that it was difficult even for the eye to follow them. She appeared, Mr. Hunter says, absolutely to be looking backwards and forwards, and in every direction, at the same moment. This woman had sometimes fifty paroxysms of this kind in a day, which greatly exhausted her: but she was perfectly rational in the intervals. A modification of the same kind of affection took place in a most extraordinary case recorded by Dr. Watt, of Glasgow, in the fifth volume of the *Medico-Chirurgical Transactions*. His patient was a girl ten years old. First she had headache, accompanied by vomiting, and increased by the slightest deviation of the body from the erect posture, either backwards or forwards, or to one side. These symptoms lasted about a month; and during that time she lost the power of speech and of walking. At the end of that period she was seized with a propensity to turn round on her feet, like a top, with great velocity, always in one direction; and was pleased when those about her assisted in increasing the rapidity of her movements. After continuing nearly a month, these motions ceased, the headache returned,

and she became unable to move her neck, or support her head. Soon after she was seized with a new kind of motion; she would lay herself across the bed, and turning round like a roller, move rapidly from one end of it to the other. At first the fits of this kind lasted two hours; but they gradually increased to six or seven hours every day. On being carried into the garden she rolled rapidly from one end of a walk to the other: and even when laid in the shallow part of a river, though on the point of being drowned, she began to turn round as usual. The rotations were about sixty in a minute. She made little or no use of her arms in revolving. In about another month or six weeks an entirely new set of movements began. She lay upon her back, and, by drawing her head and heels together, bent herself like a bow, and then allowing her head and heels to separate, her buttocks fell with considerable force upon the bed. She repeated these movements ten or twelve times in a minute, first for six hours daily, and at length for fourteen. After another space of about five weeks had elapsed, the most singular freak of all ensued; she was seized with a propensity to stand upon her head with her feet perpendicularly upwards. As soon as the feet were elevated in this manner, all muscular exertion seemed to be withdrawn, and the body fell down as if dead; her knees first striking the bed. This was no sooner done than she instantly mounted up as before; and continued to do so from twelve to fifteen times in a minute, for fifteen hours a day. After a variety of fruitless treatment, a spontaneous diarrhoea came on, and she recovered.

The spinning motions observed during a part of this case have been observed in other instances.

In Magendie's *Journal de Physiologie*, the two following singular forms of disease are referred to. A man, after some other symptoms of cerebral affection, was seized with an irresistible propensity to move forwards, stopping only when exhausted. He would sally forth into the streets, and continue walking straight forward until he dropped down, and was obliged to be brought home in some conveyance. This man at length died, and several tubercles were found in the anterior hemispheres of the brain. Dr. Laurent, of Versailles, exhibited to the Academy of Medicine a young girl, labouring under the exactly opposite necessity. In the attacks of a nervous disease she was irresistibly propelled backwards, and with some rapidity: being unable to avoid obstacles or hollows, she received many falls and bruises in her course.

I say that histories such as I have been giving you some samples of, and those mostly in an abridged form, would sound

very like romances, if they were met with in the older authors alone, or if they were not attested by unimpeachable authority. They resemble chorea in this respect, that they are examples of muscular actions performed by persons in possession of consciousness, and performed in spite of themselves. But in most other respects they differ from what we now-a-days mean when we speak of chorea. Perhaps they may rank among *hysterical* vagaries. It is remarkable that the majority of them occur in young women, in whom the menstrual function is suspended or irregularly performed. Some persons may consider them as varieties of insanity. The patients certainly did not *feign* to be ill, for the feats of strength and agility which many of them performed were much beyond their natural power or endurance. The truth seems to be, that there are innumerable modifications of the nervous functions, and that some of them are more common and more capable of being arranged into groups than others; but that they all offer points of resemblance, like (as I observed before) the different members of a large family, of which the individuals have the same general cast of features, and yet preserve each his particular identity.

I advert to these odd forms of disease with the view of directing your attention to such of them as may come in your way. We are yet terribly in the dark about morbid affections of the nerves, both organic and functional. Hereafter a medical Newton will arise, and reduce all these apparently complicated phenomena to some simple law. At present all that we can do is to collect and, as far as we may, to arrange facts, in the hope that at length some better light will be shed upon the subject. And it must be observed that some of the modern researches into physiology do throw a little glimmering of illumination into these dark corners of pathology.

In certain of M. Magendie's experiments on animals the following curious facts were ascertained:—When a vertical section of the cerebellum of a rabbit was made, leaving one-fourth of the whole adhering to the crus of the right side, and three-fourths to the left, the animal rolled over and over incessantly, turning itself towards the injured side. The same phenomenon occurred upon the division of the crus cerebelli. The animal lived for eight days, and continued during the whole of that time to revolve upon its long axis, unless stopped by coming in contact with some obstacle. How like is this to the symptoms exhibited at one period in the girl whose case is related by Dr. Watts! Nor is Dr. Watts' case a singular one: M. Serres has described another much like it. A shoemaker, 68

years old, of intemperate habits, after one of his debauches exhibited a kind of drunkenness which surprised his friends. Instead of seeing objects turn round him, as a drunken person is apt to do, he thought he was himself turning, and soon began to revolve; and this lasted till he died: and when his head was examined, extensive mischief was found in one of the peduncles of the cerebellum.

Again, M. Magendie noticed that when the upper part of the cerebrum is gently removed in birds and mammalia, they become blind; but no affection of the locomotive powers is produced. No farther result is occasioned by the removal of a portion of the grey matter of the corpus striatum: but when the striated part is cut away, the animal immediately darts forward with rapidity, and continues to advance as if impelled by some irresistible force, until stopped by an obstacle; and even then it retains the attitude of one advancing. The experiment was tried with the same result upon various species of animals—dogs, cats, hedgehogs, rabbits, Guinea pigs, and squirrels. It seems that there are horses that cannot *back*; although they make good progress enough in a straightforward direction. Now Magendie says that he has opened the heads of such horses; and has always found, in the lateral ventricles of their brain, a collection of water, which must have compressed and even disorganized the corpora striata. It has further been found, by the same experimenter and by others, that certain injuries of the cerebellum cause animals to move backwards contrary to their will; if the tail of the animal so mutilated be pinched, he still persists in his retrograde course. Injuries of the medulla oblongata had the same effect: pigeons into which he forced a pin through that part, constantly receded for more than a month, and even *flew* backwards. A section of the medulla oblongata, where it approaches the anterior pyramid, gives rise to a movement in a circle, like that of a horse in a mill: the animal, in its walk or its flight, bearing round continually to the injured side. Surely we have, in these facts, supplied by experiments on living animals, and by observation of the phenomena of disease in the living human body, some of the *materials* for a more exact knowledge, both of the physiology and of the pathology of the nervous system, than we have yet reached. M. Magendie supposes that different portions of the encephalon are endowed with energies which tend to cause motion in various directions; that in the healthy state these balance each other, and that a preponderating impulse can be given to any one of these forces by the will; but that when the equilibrium is destroyed by disease, the will is not sufficient to counteract the tendencies which are then

brought into play. Mr. Mayo offers a different explanation of the phenomena. He supposes that the injuries inflicted on the nervous matter produce a sensation analogous to vertigo; and that the animal conceives itself either to be hurried forward, and makes an exertion to repel the imaginary force; or to be moving backward, or turning round in one direction, and endeavours to correct this by moving the corresponding muscles. Whatever may be the true explanation, the facts themselves are abundantly curious and interesting, and I recommend them to your attention.

Some of the affections that I have been describing, fall, perhaps, under the category of those to which the appellation of the *leaping ague* has been given in some parts of Scotland. There is a class also of convulsive spasmodic affections which resemble epilepsy on the one hand, and chorea on the other, or rather form a link of alliance between the two, and which are especially remarkable for this, that they are capable of being propagated by that kind of imitative contagion of which I have several times spoken. This point might be well illustrated by the history of various sects of religious enthusiasts. One or two of those enthusiasts have apparently at first worked themselves up into a state approaching to epilepsy, accompanied even by insensibility sometimes; and then this state has been communicated by sympathy to the more susceptible of their auditors. I must not however go into any farther details on this subject; and perhaps I have prosecuted it too far already: those among you who are inclined to pursue it farther may find some curious accounts of an epidemic which occurred in Lanarkshire, under the head of the "Conversions of Canbuslang," in Sir John Sinclair's *Statistical Account of Scotland*; and in one of the early volumes of the *Edinburgh Medical and Surgical Journal*, Dr. Robertson has described, in an inaugural dissertation *De Chorea Sancti Viti*, a similar epidemic, which occurred in the states of Tennessee and Kentucky, in the western districts of America. This also is referred to in the same volume of the journal. Among other things Dr. Robertson says, that while extravagant sounds, and actions, and gesticulations, were in the first instance *wifful*, the actors "at length, to their own astonishment, and the diversion of many of the spectators, continued to act from necessity the curious character which they had commenced from *choice*." I will only remark farther of such forms of nervous disease, that as they spring often from moral causes, so they admit, in a great degree, of moral remedies. The pranks played by the Scotch enthusiasts were brought to an end by threatening to duck every one who should thereafter be at-

tacked; and, I believe, a few of them were horse-pounded, by way of example. With respect to the solitary instances of perverted locomotion, our business must be to correct whatever is wrong in the state of the bowels; in women, to amend the disordered uterine functions; to strengthen and confirm the system generally; and, in addition to the measures proper to effect these objects, I suspect that the cold sousing would in many cases be found of most material service.

ON

CERTAIN PHYSIOLOGICAL INFERENCES

WHICH MAY BE DRAWN FROM THE STUDY OF

THE NERVES OF THE EYEBALL.

By W. P. ALISON, M.D.

Professor of the Theory of Medicine, University of Edinburgh

[Concluded from page 384.]

III. Let us next attend to the information given by the study of the nerves of the eye, as to the influence and use of the ganglia of the sympathetic nerve, of which it is generally admitted that the ciliary ganglion, furnishing the ciliary nerves, and through which the iris is moved, is a specimen and representative.

On this subject there has been much discussion at different times, which may be set aside as irrelevant or hypothetical, because proceeding on the supposition, that part of the office of the sympathetic, as of other nerves, is to *give* the vital power or energy to the muscles it supplies. It has always seemed to me extremely improbable, that any one of the solid textures of the living body should have for its office to *give to any other* the power of taking on any vital action; and that the only doctrine on this subject which involves no hypothesis, is that of Haller, who regarded every part of the body which is endowed with irritability, as possessing that property in itself, but subject to excitement and to control, of one kind or another, from the nervous system; and the nervous system as exercising that control chiefly, and in the natural and healthy state probably only, in so far as it is the seat and the instrument of mental acts.

This doctrine, excluding the larger masses of the nervous system from all share in bestowing the property of irritability or vital energy on muscles, has received, as it seems to me, the only confirmation of which, in the present state of our knowledge, it stood in need, from the experiments of Dr. Reid,

which were laid before the British Association in 1834, and have since been repeated on warm-blooded as well as cold-blooded animals. These experiments prove, that after the irritability of muscles has been, as nearly as possible, extinguished by irritation, it is perfectly recovered by rest, notwithstanding that all their connections with the brain and spinal cord have been cut.

There is, however, nothing hypothetical or visionary in the assertion as to the nerves, that "*Soli in corpore, mentis sunt ministri*;" and, therefore, when we observe that all the great organs of involuntary motion, and among others the iris, have nerves which have passed through ganglia, and when we remember that all those organs are beyond the power of the *will*, but are peculiarly liable to control from certain *involuntary* acts of mind, particularly from sensations and emotions, our business is to inquire whether there is any thing in the structure of those parts of the nervous system which can be supposed to unfit them for the one of those offices, and fit them for the other. And if we keep steadily in mind this precise object of our inquiries, we shall find the subject less obscure and intricate than it has often been thought.

When it is stated that the nerves which pass through the ciliary ganglion supply the only muscle in the eyeball, the actions of which are truly involuntary,—that all the truly involuntary muscles of the body have in like manner nerves which pass through ganglia,—and, farther, that all these ganglia appear, from the most recent and careful examination, to be, like the ciliary ganglion, formed of filaments both from the motor and sensitive nerves, it is impossible to doubt that much of what can be ascertained as to the office of this ganglion in the eye must be truly applicable to the other ganglia supplying involuntary muscles in the body.

If we were to assert, however, that all nerves which excite involuntary movements in the body, in obedience to sensation or emotion, are ganglionic nerves, or that it is through ganglia only that these involuntary acts of mind affect the body, we shall be immediately met by various examples of sensations (or the nervous actions which attend sensations) certainly exciting movements through motor nerves destitute of ganglia. Of this the portio dura and phrenic nerve furnish sufficient examples.

But setting aside the supposition that the ganglia are necessary to enable the involuntary affections of mind to act on the muscles, let us inquire how far the opinion long ago stated by Dr. Johnston and others is correct,—that the ganglia intercept the influence of the will,—prevent the voluntary acts of

mind from acting on the muscles which have their nerves only through them.

A decided opinion is given against this supposition, both by Muller and by his very intelligent translator Dr. Baly. The reason given by Müller is this, that as we know from the experiment formerly mentioned of forcibly acting on the muscles of the eyeball, and thereby causing contraction of the iris, that a *motor* influence can traverse the ciliary ganglion, there is no reason to suppose that a *voluntary motor* influence should be arrested in it, if really brought to it. He considers it, therefore, more probable, that the fibres of the "sympathetic, at their origin in the spinal cord and brain, are not in communication with the source of the voluntary influence;" *i. e.* that they are not set on the fibres by which the will acts downwards from the source of voluntary power; to which Dr. Baly adds, that to suppose the admixtures of other fibres in the sympathetic to have the effect of removing the motor cerebro-spinal nerves from the action of the will, is in opposition to one of the fundamental principles in physiology, that of the course and influence of nerves in their "peripheral part," *i. e.* at a distance from the brain and spinal cord, being *insulated*,—*i. e.* admitting of no admixture or transference of power from one filament to another. These authors, therefore, regard the ciliary nerves as beyond the influence of the will, by reason of the mode of their origin, not of their passing through the ciliary ganglion.

But, on the other hand, if we attend to the experiment insisted on by Müller, we shall see that its result is not correctly stated by his expression, that it shews that a *motor* influence can be transmitted through a ganglion, and therefore gives us reason to presume that an effort of volition could traverse the ganglion also, if really carried to it. When the third nerve transmits an effort of volition to the muscles of the eyeball, and at the same time causes contraction of the pupil, it is plain that the influence which affects the iris has originated in the "source of *voluntary* influence" in the brain,—that is, not only a motor influence, but one consequent on a voluntary effort, which has traversed the ciliary ganglion. The ganglion has not prevented the influence of volition from acting on the nerves and muscular fibres which it supplies, although the will has no power of regulating the movement of these fibres; and this being so, I do not see how it can be denied that it has modified, in one way or other, the endowments of the nerves entering it; rendering them incapable, not of transmitting the influence of the volition, but of obeying any specific efforts of the will.

In fact, if it were in consequence of their roots having no connection with the motor portion of the brain and spinal cord, that the ganglionic nerves in the eye or elsewhere are not obedient to the will, and if the nerves underwent no change of endowment in the ganglia, we do not see why the motor nerves of the involuntary muscles (*e. g.* the motor filaments of the ciliary nerves) should pass through ganglia at all; they would be fitted for their function merely by their mode of origin.

Nor does it seem to me difficult to define a little more precisely the modes in which, in this as in other instances, by the connection established in every one of the ganglia of the sympathetic between motor filaments from the anterior, and sensitive filaments from the posterior, column of the spinal cord, the involuntary muscles, although we believe them to be supplied with motor nerves through the ganglia, are withdrawn from the power of the will.

1. Even if we implicitly rely on the experiments of Valentin and others in Germany, tending to correct the previous statements of Haller, Bichat, Wilson Philip, Mayo, and many others, and to shew that all the involuntary muscles may, under certain circumstances, be excited by physical irritations applied to their nerves*,—yet I think it cannot be doubted (from the negative result of so many experiments made previously by so many experienced physiologists) that the power of the motor nerves to excite muscular contraction is *greatly diminished* by passing through ganglia. The contractions, so excited in involuntary muscles in these experiments, have followed irritation *above* the ganglia, or even in the central masses, much more surely than in the nerves *below* the ganglia; and their force, and the certainty with which they can be produced, are certainly much inferior to those of the contractions excited by similar means through nerves not ganglionic, *i. e.* voluntary muscles.

2. The vital agency of the *sensitive* nerves passing through the ganglia seems also to be much modified; they certainly do not show on irritation, when in the natural state, nearly as much sensibility as other nerves; and their grand peculiarity seems to be, that although supplying the muscular fibres, they are incapable of transmitting those muscular sensations by which, in the case of the voluntary muscles, we are continually informed of the contractions we excite. Although the study of the eye teaches us that the influence of volition can traverse a ganglion, yet in no one instance in the body is this influence *felt to be exerted* on muscles placed beyond ganglia. And when we reflect

on what has been said of the importance of the resulting and guiding sensations, in *insulating and directing* the efforts of the will, we shall easily perceive that the want of any such sensations in the present case, is sufficient to explain the inefficiency of voluntary efforts over those muscles. These seem to be results of the degree of intermixture of the motor and sensitive filaments (with the interposition of grey matter), which takes place in the ganglia, instead of taking place at the extremities of the nervous filaments in the muscular fibres themselves.

It is very well worthy of notice that there is one action of the eye, in which the ciliary nerves are essentially concerned, and in which there is a distinct *resulting sensation* consequent on their action, and in that action the ciliary nerves and the iris may be said to act in obedience to the will: I mean that still mysterious effort, whereby the eye increases its own refracting power, and so enables the rays from an object brought gradually nearer it, to form a distinct image on the retina, and excite a distinct sensation in the mind; which effort is uniformly coincident with a gradual contraction of the pupil. Here an effort of volition is made in the direction of the eye, and the continued gratification of the sense, resulting from that effort, in so far as it affects the refractive power, seems to act the same part there, as the gratification of the sensations in the chest, in regulating the contractions of the muscles of respiration.

However, I am aware that objections may be stated to these speculations; and probably it is wiser to rest at present on the general inference, deducible from a comparison of the ganglionic nerves of the eye and of other parts, that when the sensitive and motor filaments which connect a muscle with the spinal cord meet in a ganglion before reaching the cord, their endowments are so far modified that the sensations thence resulting are rendered less precise; that the efforts of the will cannot be insulated on such a muscle, and, therefore, although capable of being influenced by the will, it is truly involuntary.

But it is obviously part of the design of nature, in the construction of the ganglionic nerves, not only that they should withdraw the muscles they supply from the dominion of the will, but likewise that they should facilitate and increase upon them the power of what I have elsewhere called sensorial influence, *i. e.* the influence attending or resulting from sensations and emotions of mind, which we know to originate, or to be excited exclusively, in the larger masses of the nervous system, and to act with peculiar power on muscles and other organs which have their nerves through the ganglia. Here also the study of the eye gives us important information.

* See Valentin De Functionibus Nervorum, &c. p. 62.

The ordinary action of the iris, in obedience to the stimulus of light, is certainly effected by a reflex action, in which the optic nerve, the corpora quadrigemina, and the third nerve, are concerned, and which has been fully illustrated by the experiments of Mayo, Flourens, Valentin, and others. That the peculiar sensation of light, excited by the impression on the corpora quadrigemina, not only attends the action but regulates its degree, is at least highly probable; although it is right to admit, that the action occurs occasionally in cases of amaurosis, where the patient expresses himself as conscious of no sensation; and I do not think that there is so good evidence of the necessary interposition of mental changes in this action, performed by an involuntary muscle, as in the cases where selected and regulated contractions of voluntary muscles are excited by the reflex function of the cord, as, *e. g.* in the contraction of the orbicularis oculi and of this muscle only, effected through the seventh nerve, on the same sensation being felt.

As the third nerve appears to have roots in the posterior as well as anterior portion of the crus cerebri, it is certainly quite possible that those of its filaments which enter the lenticular ganglion are set on sensitive, not on motor portions of the cerebro-spinal axis; but if so, the observations already made show that they are capable of being excited by an influence acting downwards from the strictly motor portions.

The indirect and probably modified influence, resulting from volition, and transmitted through the ganglia to the involuntary muscles, and of which we have this unequivocal example in the eye, is in itself in all probability an important part of the design of nature in the construction of the sympathetic nerve and its ganglia. I perfectly agree with Müller that it is in this way only that the effect of muscular exercise on the action of the heart, and much of the beneficial strengthening effect of exercise, is to be explained; and this indirect influence of voluntary muscular exertion on the heart is obviously important, as keeping its actions in unison with any occasionally required increase of voluntary muscular exertion; and so enabling us to keep up exertions which must otherwise have failed. And a slighter degree of the same indirect influence of exercise is seen in the movements of the stomach and intestines, which become to a certain degree torpid from inactivity of the voluntary muscles. For this slighter agency of voluntary exertion on the moving organs supplied by the splanchnic nerves, there is probably provision made, in these nerves passing through a greater number of ganglia, before they reach the moving fibres, than the nerves of the heart, and therefore having

the indirect influence of the voluntary efforts transmitted through them in a less degree of intensity.

But it is very important, in reference to the use of the ganglionic nerves, to observe, that the movement of the iris is capable of being effected, not only through the third nerve, but likewise through the fifth nerve and the sympathetic, *i. e.* by all the filaments which form part of the composition of the ciliary ganglion. I shall not enter on the observations which have been made on the differences observed in different muscles in this respect; nor on the speculations of some German physiologists as to the mode of action, particularly of the sympathetic, on the iris; but only observe that the effect chiefly observed from the section of both these nerves on the iris, is a gradual and permanent contraction of the pupil. The influence of both these nerves on the iris is therefore strictly analogous to the kind of influence observed in experiments on animals, from injury of different parts of the nervous system, or the sympathetic nerve, on other involuntary muscles, consisting, as Müller states, "either in enduring contractions, or in a long-continued modification of the ordinary rhythmic action of the organ;" a change, *e. g.* in the number and rapidity of the beats of the heart, or of the peristaltic movements of the intestines; in short, as Haller long ago expressed it, a change of the property of irritability itself, as resident in these muscular organs.

Now, when we apply these observations generally, to the living actions of those muscles which have their nerves from the sympathetic, I think we can be at no loss as to the use of great part, at least, of the structure of this part of the nervous system. These nerves place the organs which they supply in connexion with the whole extent of the cerebro-spinal axis: we know, from the observations now stated as to the iris, that an influence may be transmitted to these organs through any of the nerves entering any one of the ganglia; we know, from such experiments as those of Le Gallois and Dr. Wilson Philip, as well as from the effects of injuries on the human body, that injuries acting on any large portions of the brain or spinal cord, affect the heart at least, if not other of these organs, nearly alike; we know that, in the natural state, all these organs are peculiarly under the control of what I have called *sensorial influence*, *i. e.* an influence resulting from those changes in the nervous system which attend intense sensations and emotions of mind; we know, from various facts, some of which I have elsewhere collected*, that this sensorial influence, although often originating from an

* Outlines of Physiology, p. 398.

impression made on a single point, extends itself rapidly in different directions through the nervous matter, and that it can cross from the sensitive portions of the nervous matter to the motor portions, probably at any part of the spinal cord. The effect of any arrangement which brings a particular muscle into communication with many points of the cord, must be still more decided in regard to this sensorial influence, than as to the influence of volition as affected by a plexus. The purpose of the multiplied origins of the spinal accessory nerve, which appears, from the experiments of Valentin and others, to transmit an influence to a greater number of nerves, connected with the cervical plexus, than had been formerly suspected, and therefore to be essentially concerned in many complex actions consequent on sensation and emotion, is thus easily understood. Some observations already published by Dr. Reid, shew more precisely that in the case of the heart, just as in the case of the iris, the sensorial influence, or one exactly similar to it, affecting the contractile power of the muscle, may be transmitted through different nerves entering the ganglia, and so passing to the muscles; for he found that a violent blow on the head influenced the actions of the heart much less, when the sympathetic and par vagum were cut in the neck, than when these nerves were entire, shewing that a part of that influence passes through these nerves; and on the other hand, he found that when an animal in which these nerves had been cut was under the impression of fear, its heart's actions were quickened nearly in the usual way; shewing that another part of that influence must pass through other nerves. It seems impossible to miss the conclusion, that the arrangements and the communications to those ganglionic nerves are designed and adapted, according to the laws of nervous action,—while they intercept the direct influence of the will,—to multiply and concentrate, on all the organs they supply, that equally certain, equally important, and more varied and extended influence which results from sensations and emotions of mind. And I think it appears clearly, from what has been said, that these are objects which the arrangements of this part of the nervous system must necessarily be so disposed as to secure.

IV. The last question which I shall here consider as elucidated by what we observe in the eye, relates to the mode of transmission of that sensorial influence, resulting, in the natural state, from mental sensations and emotions, which affect the organic functions of nutrition and secretion, and, in all probability, the vital properties and composition of the blood itself, in all parts of the body.

It has been long known that the lacrymal gland is supplied so completely by the fifth nerve, that it must be through a branch of this nerve, almost exclusively, that the passions of the mind, or the sensation of pain excited in other parts of the body, must produce their effects on the flow of tears; and the experiments of Magendie, in which inflammation and ulceration of the conjunctiva and cornea, and ultimate collapse of the eye, followed section of this nerve, and some cases presenting the same series of phenomena in the human body (of which I have myself seen two), have shewn that the nutrition of the whole eyeball, and especially the secretion of mucus on the conjunctiva, are under the control of this nerve. It is hardly necessary to say, that the common expression of this nerve "presiding over these functions," is vague and unsatisfactory; but that it is the nerve destined to affect these functions, in the way in which nature intends them to be affected by changes in the nervous system, is sufficiently obvious, and is another general principle derived from observations on the eye, and manifestly applicable to the nerves of common sensation all over the body. I have formerly stated a conjecture, which I still think the most probable explanation of the inflammation excited by disease or section of this nerve, viz. that the sensitive nerve, which Sir C. Bell has well denominated the "guard of the organ," having thus lost its power, the irritations which, in the natural state, are applied to the mucous membrane, and by an action there, attended with sensation, determine a sufficient flow of the natural protecting mucus, now lose their effect, and the membrane is reduced nearly to the condition of a serous membrane, and inflames (as all serous membranes do) merely from the contact of the air.

This influence of sensitive nerves and of sensations, and this consequence, of the want of such influence, I take to be an important point in the physiology of other mucous membranes as well as this; but we are more immediately concerned with the question, in what manner the fifth nerve is qualified for transmitting downwards the effect which sensations, even in distant parts of the body, and emotions or passions of the mind, have on the circulation through the eye, and on all its secretions.

The instance of the lacrymal gland, and of the mamma, (which, according to the directions of Müller, has its nerves merely from the intercostals, to the exclusion of the sympathetic), are enough to shew, that the most intense agency of mental emotion may take place through the nerves of common sensation.

I think Dr. Marshall Hall has good reason for the opinion which he has stated, that as

the nerves which supply most of the internal organs of secretion, and of organic life in general, are ganglionic, and as the circulation in the eye itself is liable to influence from section of the sympathetic nerve as well as of the fifth, it is probable that the Gasserian ganglion, and the ganglia on the sensitive roots of the spinal nerves generally, must be designed for the influence of these nerves on secretion and nutrition, not for their functions in regard to sensation; but it seems to me much more doubtful whether Müller is right in his conjecture that the *grey matter* of the ganglia, and the grey fibres passing from them along the nerves, are the parts of the nervous system designed exclusively to affect the organic functions of secretion and nutrition. There are no experiments to shew any such peculiar power in the grey matter of the nervous system; and I can state one fact which shews unequivocally that if it is, as Müller supposes, through the grey matter in the Gasserian ganglion, and of the branches of the sympathetic which communicate, beyond that ganglion, with the fifth nerve, that any emotions or sensations affect the secretions of the eye, that grey matter must itself be acted on by the substance of the fifth nerve behind the ganglion. For in one of the cases of palsy, affecting the fifth nerve on one side, which was long under observation in the clinical ward, it was quite obvious that neither emotions of mind, nor sensations excited in the sound nostril, or in other parts of the body, affected the eye of the palsied side, which, although inflamed, remained always dry when the other was suffused on such occasions. Now, in this case it was ultimately ascertained by dissection, that the diseased (and ultimately wasted) portion of the nerve was behind the Gasserian ganglion, between it and the origin on the crus cerebelli, from which it appears quite certain that the influence of mental sensation and emotion must pass downwards through this portion of the nerve (which I believe hardly contains any grey fibres) on its way from the sensorium commune to the eyeball.

Whatever may be the use of the grey matter in the ganglia, or in other parts of the nervous system, I think we cannot doubt there is here a grand exception to the principle which has been laid down by several authors, that the same nerve is never employed to convey impressions upwards to the sensorium and downwards to the extremities of the nerves. At least, if there be a set of nerves destined solely to convey the influence of sensation and emotion downwards to the organ of organic life, these nerves are every where bound up in the same sheath with the nerves of common sensation, by which impressions are carried upwards to the brain.

Thus the study of the nerves of the eyeball enables us, I think, to give a decided opinion as to the following points;—

1. That all strictly animal muscular movement is not only excited, directly or indirectly, by sensations producing it, but is continually guided and regulated by sensations which succeed and result from it.

2. That it is the province of these resulting sensations, *commencing or anticipated*, to determine on individual muscles the influence of the will; and where distinct animal movements are always consentient, it is because the sensations thus guiding them are the same.

3. That neither the connections of nerves at their roots (so far as anatomy has detected them), nor the plexuses which they form in their course, can be assigned as the cause of consentience of their movements, or of any combinations of their actions; but that the plexuses of nerves, placing both the sentient and motor nerves of the muscles of the extremities in connection with a large surface of the spinal cord, seem to be designed and fitted to render the muscular sensations more distinct, and the acts of the will more energetic, than they otherwise would have been, and thereby to give power, facility, and precision, to the combinations and successions of muscular contractions in all movements of the limbs.

4. That the action in nervous matter, which is excited by an act of the will, can traverse a ganglion, but is never felt to be exercised, and therefore cannot be applied to any specific object, beyond it, apparently because of a modification of the endowments, both of sensitive and motor filaments of nerves, where they are subdivided and intermixed with the grey matter of a ganglion.

5. That the motor filaments of nerves which have passed through ganglia may be affected by changes in the sensitive as well as the motor filaments which enter the ganglia; and that in this way, probably, the influence of sensations and emotions of mind (which must be transmitted through the ganglia, because it affects especially muscles which have only ganglionic nerves), is conveyed from many parts of the spinal cord, and concentrated on the muscles of organic life.

6. That the influence of changes in the nervous system, and especially of such as accompany sensations and emotions of mind, on the capillary circulation, on the functions of nutrition and secretion, and on the properties of the blood, may be transmitted downwards by the nerves of common sensation, and that it is probably with a view to this influence that the ganglia are formed on the roots of those nerves.

ON STAMMERING,

AND THE METHODS PROPOSED FOR ITS
REMOVAL.

By EDWIN LEE, Esq.

[Concluded from p. 390.]

[For the Medical Gazette.]

WITH regard to the methods of education, the object of which is to regularise the respiration and the action of the different parts concerned in speech, and thus bring them to act in harmony together, there is no doubt that they are calculated to effect the removal of the complaint in a large proportion of cases; but when we consider the length of time required, the subsequent attention necessary to prevent a recurrence, and the power of habit, we cannot feel surprised that many persons should be unwilling to have recourse to them, and that relapses should frequently occur; for the statistical accounts of teachers and practitioners of these methods cannot always be relied upon, on account of the difficulty which must exist in keeping the patients in view for a sufficient time after the termination of the treatment; and if the opinions which I have expressed of the varieties of stammering be correct, there are obviously cases in which these means would be attended with no advantageous result, though all are undertaken indiscriminately. This mode of treatment I should conceive most likely to be attended with success in the nervous kind of stammer, particularly when it has arisen from imitation, and in those cases where there exists little or no physical alterations of the tongue or throat: but even in these it will fail in a certain proportion, and relapses must not unfrequently occur: so that, as stammerers have now other means within their reach by which they might frequently be relieved, it becomes a matter of choice for them to which they would prefer having recourse; but "*l'un n'empêche pas l'autre*," and many individuals whom treatment has failed to relieve may still be cured by operations which are not particularly serious, and in the vast majority of cases entail no unpleasant consequences. And again, in some of those who have undergone operations, educational methods may be had recourse to with advantage when the operation has not

succeeded in removing the infirmity, or has been attended with only a partial success. Having just said that the operations are not generally serious, or followed by unpleasant consequences, I of course do not include that of Professor Dieffenbach, which I consider to be attended with considerable danger, and only to be thought of in extreme cases, when the patient is willing to run the risk; and I have no doubt that many, if not the great majority, of the patients so operated upon would have been relieved by the other operations. It has, I believe, only been performed once in this country, by Mr. Lucas—after the failure of the other operations—with success; and we have seen that the operation by the ligature, by M. Velpeau, appeared to be equally efficacious; though this also is a proceeding by no means to be recommended. Indeed, the hæmorrhage is almost always profuse, and has occasioned the death of one patient, a medical student. Even Professor Dieffenbach speaks of it in such a manner as not to recommend its adoption, unless by very skilful operators. He says, "The importance of so serious an operation, the dangers which may result from it, the loss of the tongue by mortification, a too abundant suppuration, or even the unskilfulness of an assistant, which may cause it to be torn, are so many considerations which require to be fully taken into the account, and which, joined to the difficulty of its performance, will prevent its being undertaken by unskilful operators." The cases in which it might be admissible, and most likely to be attended with relief, are those in which the tongue is of very large size, which impedes the harmonious action of this organ with the other parts concerned in speech.

The division of the genio-glossi muscles or of the frenum and sublingual mucous membrane, on either side, is the operation which I have seen most successful; and in which the success has been the most permanent in bad cases of stammering. I consider that the method of performing it by the mouth is preferable to the subcutaneous operation, not only because it is more easy, and because it may be ascertained with the finger whether all the fibres are divided, but likewise because in a certain number of cases the division of the membrane is sufficient, and the

patient is spared the pain and inconvenience of the second part of the operation. It may be that the three first patients on whom M. Bonnet operated were not completely relieved of the stammer, because the muscular fibres were not entirely divided, as in the last two patients; or it may be, that being of the purely nervous kind, this division of the muscle is not so well calculated to remove the stammer as in the physical kind, where the movements of the tongue are limited, or this organ is more fixed than natural to the floor of the mouth, so as to prevent its being duly protruded. The section of the membrane or muscles of the mouth I conceive to be also best adapted to the third kind of stammer, when there is a combination of the nervous and physical varieties. The chief objections to this operation are the bleeding and inflammation sometimes occasioned by it. In the great majority of cases these accidents do not occur to any prejudicial extent; and by keeping the edge of the knife or the blades of the scissors near to the bone, the risk of bleeding is greatly obviated, as there are only small vessels at this part, though they may in some cases become anormally enlarged, in proportion as the muscles themselves are enlarged. Several of the patients at M. Amussat's lost a few ounces of blood before the bleeding ceased by the application of ice. Hæmorrhage to a considerable extent occurred in one case of Mr. Phillips, but was not followed by any bad consequences. A case likewise happened to myself, in which at least ten or twelve ounces of blood were lost before the bleeding ceased. The muscles of the tongue, and beneath it, were very much developed in this case. The patient's pulse was quick and full, and the bleeding did not induce faintness, so that I consider it was rather beneficial than otherwise. This was a bad case of mixed stammer; the patient being of a very nervous temperament. The stammer was a good deal relieved, but he still stammers much when excited.

A case of alarming hæmorrhage recently occurred to M. Guersant, but it is not attributable entirely to the operation, as there existed in the boy a hæmorrhagic diathesis, of which the operator was not previously aware. He was subject to repeated bleedings from

the nose, and, only a few days before, the extraction of a tooth had given rise to troublesome bleeding. There was very little loss of blood at the time of the operation, but it took place subsequently, and the greatest quantity of blood was lost three days after the operation, so that it did not occur from the division of any particular artery. The actual cautery was twice applied, ice and other means having been previously found ineffectual; but the hæmorrhage ultimately ceased, and the boy's pulse was not particularly depressed. M. Guersant had performed the operation on nine other individuals, who considered themselves relieved by it, but the amelioration was not so apparent to M. Guersant. In one of the patients, who experienced the greatest benefit immediately after the operation, the stammer gradually returned as bad as ever. In that case also, where M. Velpeau excised a triangular portion from the apex of the tongue, the advantage resulting from the operation was not permanent; so that in these cases mental impression must be considered as the cause of the immediate advantage, as it is evident from M. Velpeau's account that there was no physical alteration of the tongue itself; and I purposely mentioned the case of epilepsy, in which he tied the facial and temporal arteries, (as well as those of aphonia cured by mental impressions, in the beginning of this paper) in order to illustrate the power of similar agencies over nervous diseases. Almost every practitioner is aware that the attack of epilepsy may frequently be suspended for a longer or shorter period by any means in which the patient can be induced to have confidence: hence the histories of cures of this disease from animal magnetism, as well as from the host of drugs which have in turns been cried up as specifics, but which have only enjoyed an ephemeral reputation. Any thing tending to break the chain of habitual recurrence will also very frequently produce a similar effect; as a burn or other accident. And there is not the slightest doubt but that in a great many of the cases of stammering which have been cured by operation, the advantage may be satisfactorily accounted for in this manner; but, on the other hand, there is no doubt that the operations act in

many cases by removing physical impediments to the associated and harmonious action of the parts concerned in speech, as in many of the individuals whom I have observed, especially in Paris, where in almost all those persons whom I saw, some degree of shortening, thickening, or other anormal condition of the tongue existed, (which has led M. Amussat to conclude that stammering depends invariably upon the anormal states, but which, I have no doubt, are, in the majority of cases, consecutive on the nervous kind of stammer, as I have already said), and almost all of whom were either cured, or derived more or less permanent advantage from the operation. In one patient, whom I examined, where it failed to afford any relief, the tonsils were considerably enlarged, which shews the necessity of discrimination. The nine cases operated by M. Guer-sant, in which he did not think any very marked benefit was produced, were likewise in all probability not so well suited to this kind of operation. The circumstance, which I witnessed several times, of the stammer being partially remedied on the section of the sublingual membrane, still more so when the muscles were partially divided, and altogether removed after the division of the muscular fibres which remained attached to the bone, suffices to show the material action of the operation in some cases where the movements of the tongue are not particularly limited: yet, in a large proportion of cases, its muscles are unduly developed, and contract energetically on the introduction of the finger, and consequently, on attempting to articulate particular letters or words which require their active concurrence: here, I conceive, the operation produces a beneficial effect by removing this state of anormal contraction and rigidity, producing a degree of relaxation, (to which likewise the loss of blood is favourable), which enables this organ the better to act in unison with the muscles of the throat and of respiration. Dieffenbach's operation tends to produce a similar result. Hence we may perceive why the spasmodic actions of the face and other parts should so speedily cease after these operations, why the excision of the uvula and tonsils should fail when there is considerable

enlargement of the tongue, or when the motions of this organ are particularly restricted.

With respect to this latter mode of operating, I am convinced that it likewise acts in many cases, though not in all, by the moral impression produced upon the patient: this will be evident on referring to two or three of the cases which I have noted, and also to those reported by Mr. Yearsley. We see in the case of Henry Gee, that he spoke much better when the palate was incised on one side; that he continued to speak tolerably well the first two days, but afterwards he began to lose the advantage, till the uvula was removed, when he again experienced a decided improvement. On the other hand, the man on whom extensive division of the palate had been made without any benefit resulting, had also his uvula removed without any advantage. In some patients the excision of a portion of the tonsil relieved the stammer, as in the case of Henry Smith. I think it not improbable that the presence of these bodies when enlarged may in some cases produce stammering (not, as Mr. Yearsley imagines, by narrowing the throat, or by preventing the free egress of air, but in a similar manner as when the muscles of the tongue are enlarged, and consequently limited in their movements, or when this organ is more bound down than natural), by interfering with the harmonious and associated action of the muscles of the palate with other parts concerned in speech. But these cases are rare when compared with others. The presence of enlarged tonsils must then be looked upon as an accidental coincidence, though when existing this enlargement doubtless tends to aggravate the stammer. In the case I have mentioned, at M. Amussat's, when the section of the genio-glossi failed to afford relief, and the tonsils were a good deal enlarged, it is very likely their removal would have been productive of benefit. This I suggested to M. Amussat, and he promised to perform the operation; but as I left Paris on the next day, I am not aware whether or not it was done. In Mr. Yearsley's case, to which I have already alluded (Crawley), it may be questioned whether the extirpation of the tonsils would not have been attended with considerable relief to the stammer, even if

the uvula had not been excised. I say this, not to call in question the propriety of excision of the uvula in this case, but as a hint for future investigations which may serve to elucidate the complications of stammering. When, therefore, in stammerers, the tonsils are enlarged, the removal of these bodies may relieve the stammer, by allowing a freer play to the muscles of the throat, by which means their action can be better associated with that of the respiratory and lingual muscles. In corroboration of what I have now stated, I may refer to the cases of Charles Geyer, (in Mr. Yearsley's pamphlet), in which the tonsils were enlarged, and the mere excision of the uvula produced no advantage; of J. Topliss, whom the excision of the tonsils sufficed to cure; and also of James Carter, æt. 12, a bad case of stammer from early childhood, in which the tonsils only were excised, with relief at the time, and progressive subsequent improvement, terminating in complete cure. I think, therefore, that in stammerers, when the tonsils are enlarged, there will often be found, in addition to the nervous stammer, a difficulty upon particular letters (the gutturals), and that the removal of the enlarged tonsils would generally be productive of as much benefit as when the uvula is also excised. The excision of this substance, or the division of the palate, may likewise act in some cases by diminishing the state of tension, or tendency to anormal contraction of the palatine arch, which occasions the impediment in articulating, when the person is in a nervous or excited state; but in many, if not in the majority of these instances, the moral impression from the operation is principally instrumental in producing the amelioration, which may be only temporary, or it may be of a permanent nature; but in whichever way it acts it is unquestionable that several persons have been cured, and many have experienced decided relief; so that in certain cases, when the division of the genio-glossi muscles, or of the membrane covering them, does not appear to be more especially indicated, I see no reason why the uvula should not be removed; for, even supposing the effect to be merely mental, that is no reason against its adoption, if the complaint can be by this means removed or mitigated, particularly if it be clear that no

inconvenience results from the loss of the uvula in those cases where it is not attended with success. In cases of purely nervous stammer it is perhaps as likely to be successful as the more severe operation of the section of the genio-glossi, which, however, I consider better adapted to the physical or mixed cases (unless when there is enlargement of the tonsils), and to those of bad stammerers, where a difficulty exists upon particular letters or words. This operation, as well as the others, no doubt also acts in some cases where nothing anormal is perceptible purely by the mental effect which is produced.

No one can have a greater abhorrence of charlatanism, or be less likely to countenance it, than myself: I therefore think it due to Mr. Yearsley (though not agreeing with him as to the nature of stammering, or the manner in which excision of the tonsils and uvula afford relief) to state my belief that he has acted with good faith in giving the correct results of his cases, as far as he was able to ascertain them; and I think that if his operation were performed with more discrimination, he would be enabled to record a greater amount of success.

ON THE DUBIOUS EFFICACY, AND NEGLIGENT PREPARATION, OF DIGITALIS.

To the Editor of the Medical Gazette.

SIR,

SHOULD the accompanying remarks on the dubious efficacy and negligent preparation of digitalis be thought of general interest, you will oblige me by publishing them in your journal.

I am, sir,

Your obedient servant,
HENRY BURTON, M.D.

41, Jermyn Street, May 14, 1841.

Believing that the efforts of physicians to cure disease have been often foiled by the use of medicines negligently prepared, I feel desirous, through the medium of your widely-circulated journal, of calling the attention of the medical profession to the dubious efficacy, and unequal strength, of the tinctures made with the leaves of digitalis purpurea, and dispensed by many druggists.

The leaves of this plant have been frequently employed, during the last

sixty years, in the treatment of various maladies, and many physicians of reputed experience have attested their curative utility. There has, however, been much difference of opinion existing between practitioners on this point; and I believe digitalis is now less frequently prescribed than it was at the commencement of the present century; but whether the disuse of this remedy is a consequence of its inefficacy under all circumstances is open to discussion, and I shall endeavour to point out one or two circumstances referrible to the collecting and preparing the leaves of digitalis, which seem to have led to the introduction of a medicine of inferior strength to that which was employed, more generally than now, at the commencement of the present century.

For the instruction of those among your readers not conversant with the facts bearing on the medical uses and preparations of digitalis which have been recorded, and as preliminary to describing my own observations, I beg to point out to them the work of Dr. Withering, published in 1785, as one which has been long considered a standard authority. A similar work was also published by Dr. W. Hamilton in 1807, on the same subject; and in these two volumes a great many authors are named who had prescribed digitalis in the treatment of different diseases with various results. The reader will derive much information from perusing these works, and by also consulting, in addition, the "Treatise on Consumption," by Dr. Young, published in 1815, in which the opinions of many other distinguished authors, for the most part favourable to the use of digitalis in the treatment of that malady, are quoted; and by perusing the valuable observations of Dr. Blackall on Dropsies, first published in 1813, he will meet with a confirmation of Dr. Withering's opinion of the benefit occasionally derived from the use of this plant in dropsies. Lastly, among the most eminent living practitioners who have written on the same topic, is Dr. Holland, whose testimony of the utility of digitalis, in the treatment of cardiac disease, and as a diuretic, is recorded in his valuable book, entitled "Medical Notes and Reflections."

In the face, therefore, of the numerous opinions recorded by these experienced

and learned authorities, due allowances being made for impartial exaggerations or misconceptions in favour of the medical utility of digitalis, it would be evincing unreasonable scepticism to doubt its efficacy in certain maladies, and I should regret to see this plant condemned as an useless medicine until all the probable sources of error attending its preparation and exhibition had been thoroughly investigated, and unquestionable proofs obtained that no reliance should be placed on the medical qualities of its most approved preparations. My own opinion is, that no sufficient evidence has been adduced of its inefficacy, and that a large share of the contrariety of opinions entertained on this point has arisen from the use of preparations which had been made with the leaves of digitalis unfit for the purposes of medicine, and I confess my own expectations of producing a beneficial effect by them have been often disappointed; but my attention has been only recently directed to the cause of this disappointment.

The value of my theoretical knowledge of the uses of this plant has been assayed during the last six years by the exhibition of its tincture to at least three hundred patients, treated by me in St. Thomas's Hospital, and to whom this remedy was given either with the intention of producing the absorption of effused serum, or of promoting the secretion of urine, or of controlling the heart's action. For several years the tincture was prescribed in the medium doses of twelve minims to twenty minims; they were repeated three or four times daily, and very frequently continued for several weeks without intermission; but notwithstanding the length of time the preparation was administered, yet in only a few cases did any necessity occur to discontinue it, in consequence of the accession of those symptoms which have been insisted upon as signals to withhold the use of digitalis. But this seeming inaction was not invariable, and, in a few cases, one or more of the ordinary effects attributed to digitalis were noticed, and in these there was either a diminution or augmentation in the force and number of the pulsations, and irregularity; or sickness, giddiness, and impaired vision; and in a few patients the secretion of urine was notably augmented. What then was the reason, it may be

asked, why, notwithstanding the statements made in favour of the efficacy of small doses of digitalis, and published by the authorities above quoted, some evident effect was not more frequently noticed in three hundred patients? Not, I believe, in consequence of inattention to the directions given by these authorities for the exhibition of digitalis; nor from a neglect to examine my patients; but after taking into account the nature of their respective diseases, their strength, ages, and peculiarity of constitution: the preparation, dose, combination, and repetition of the medicine; and comparing the effects produced under circumstances as nearly similar as the nature of medical inquiries will permit, with those under which digitalis was given by Dr. Withering, Dr. Hamilton, and Dr. Blackall, with manifest benefit, I think the absence of sensible effects in the majority of the patients treated with its tincture by me, may be justly attributed to the indifferent quality of the leaves employed in making this preparation, and to the smallness of the dose in which it was prescribed.

The former source of error was foreseen by Dr. Withering; and Dr. Holland observes, "It is certain that many of the inequalities and seeming anomalies in the effects of digitalis are owing to neglect of the qualities of its preparations." Dr. Blackall also, in speaking of the dosing with digitalis in dropsy, says, "One considerable source of inaccuracy certainly arises from the various forms in which this medicine is prescribed—of infusion, of tincture, of powder, and the extreme difficulty of making a just calculation of the relative strength of these."

Now it is manifest that unless each form is exhibited in equivalent doses, and has the same uniform strength, the effects produced by them respectively, when given in doses nominally the same, will necessarily differ, and probably occasion an erroneous judgment of the efficacy of digitalis. But the same form has not had at all periods of the history of digitalis the same invariable strength; and, with respect to its tincture, it has been made with the same kind of materials, applied in at least three different proportions, since it was first recommended by Dr. Darwin, to whom we are indebted for suggesting the use of the saturated tincture. The

tincture described by Dr. Darwin was made with two ounces of the dried leaves and eight ounces of proof spirit, or in the proportion of one ounce of the leaves to four fluid-ounces of the spirit (*Hamilton*, p. 82): whereas, in the tincture directed to be made in the London Pharmacopœia of 1824, the materials were applied in the proportion of one ounce of the leaves to eight fluid-ounces of the spirit; and in the edition of the same book published in 1836, the proportions there stated are as one ounce of the leaves to ten fluid-ounces of spirit. Now, taking as assumed facts, that all the virtues of the leaves are imparted to the proof spirit employed in making the tinctures, and that ten minims of the tincture directed to be made in the London Pharmacopœia of 1836 is a medium dose, these ten minims will be the equivalent dose of one grain of the powder; whilst ten minims of the tincture directed to be made in 1824 will be the equivalent of one grain and a quarter; and ten minims of Dr. Darwin's tincture, of two grains and a half of the powder. Hence, as equal measures of these several tinctures contain unequal quantities of the active principle, they must *ceteris paribus* produce different results when exhibited in doses nominally equal; and from the use of these dissimilar tinctures has arisen one source of the disagreement among practitioners relative to the medical powers of digitalis. It is often a point of great consequence to the success of the treatment, that the strength of similar preparations should be uniform, and the prevalent opinions respecting the medium doses of each correct. Now the prevailing opinion, relative to the medium dose of digitalis in powder, seems to have originated with Dr. Withering, and requires notice. "I give," he remarks, "from one to three grains of this powder twice a day: in the reduced state in which physicians find dropsical patients four grains a day are sufficient," (p. 181); and Dr. Blackall also observes, "that even these doses are not free from the possibility of injury, and not fit to be continued without the watchful care of the medical attendant" (page 313). Dr. Withering adds, that half a drachm of the powder, given to the extent of four grains daily for five days, may be in general taken before nausea com-

mences." But this quantity of the powder recommended by Dr. Withering, as well as that of the tincture prescribed by myself, has been much exceeded by other practitioners, two only of which it will suffice to name in evidence of the maximum quantity of each preparation which has been swallowed without injury: thus, in the *Med. and Chir. Rev.* July, 1834, notice is taken of the experiments of M. Andral, from which it appears he gave to one patient as many as 206 grains of the powder in twelve days, or at the rate of seventeen grains and a half nearly each day: and in the *MEDICAL GAZETTE*, vol. i. 1828, it is stated by Dr. Williams, that a drunken man swallowed a fluid-ounce of the tincture twice, at short intervals, without any deleterious consequences. From these statements, among many others which might be quoted, one of two inferences may be drawn; either that the doses in which digitalis was given by Dr. Withering were ridiculously small, and his authority unworthy of credit; or that the quality of the digitalis used by M. Andral, and alluded to by Dr. Williams, was comparatively speaking inert. The latter inference seems to be the most correct: for Dr. Withering, as well as other credible authorities, agree in stating, that in a great many cases digitalis has been given in small doses with manifest effects on their patients; and there is also sufficient evidence recorded of the poisonous nature of digitalis: and speaking of the danger of large medicinal doses of it, Dr. Blackall says, "the results have been some unexpected recoveries much talked of, and more failures which tell no tales" (p. 301.)

I can, therefore, only attribute the very different effects produced by the preparations of digitalis, under the direction of different practitioners, to the employment of bad leaves; leaves, for instance, which have been collected at improper periods of the growth of the plant; sometimes from the seedling root; at others, from the second year's root, before their juices have been duly elaborated: such leaves never can furnish a good active remedy, and their characters vary materially from those directed to be employed by Dr. Withering, and all the subsequent writers on materia medica, who have reiterated his instructions. I have pro-

cured the objectionable leaves from several sources for the purpose of experiments, and have compared them with those directed to be employed by Dr. Withering. "The leaves," says this author, "vary greatly in their efficacy at different seasons of the year. They should be gathered after the flowering stem has shot up, and about the time when the blossoms are coming forth." Dr. Hamilton, also, in his book on the Preparations and Uses of Digitalis, says, "The largest and deepest coloured leaves are to be selected and carefully dried."

But let the conscientious practitioner inquire when the leaves are collected, and how they are dried, and he will be much distressed to find that, instead of the leaves being gathered at the period of their growth, as directed by the best authorities, when the stem has shot up for flowering in the second year of the plant's growth, when the leaves have acquired their full development, and their juices have been duly elaborated towards the end of June and July; they are, on the contrary, gathered as Spring shoots, before any vestiges of either stem or flower have become apparent, and before their juices can have had time to be duly matured. At this period of their development the leaf-stalks rise directly from the root, and are cut in tufts consisting of the Spring leaves connected together by the upper portion of the root-stalk. The fact should be also remembered, that digitalis purpurea is a biennial plant, and does not flower in the first year of its growth. It rises from seed, and when its leaves of the first year's growth are fully developed in the autumn, they are gathered and applied to the purposes of pharmacy, in common with the young leaves of the second year's growth.

But the juices of a biennial plant do not arrive at perfection until the second year of its growth; and hence, with reference to digitalis, a double source of error emanates from the use of its leaves before the flower-stem has shot up. It would be useless to extend this communication with descriptions which may be found in every book on *Materia Medica*, of the mature leaves of digitalis, or of the modes of preparing them. I am, however, desirous of adding a few remarks on the character of the tinctures of digitalis which are dispensed

by the London druggists, with the object of enabling the practitioner to distinguish the genuine preparation from the spurious. I have recently compared together twelve different tinctures of digitalis, eight of which were procured from as many different sources, and four were made by myself; two of the four were made with the mature leaves of the plant, and two with its immature leaves.

The practical results of my observations and experiments are represented in the subjoined tabular view, and they have led to the conclusion, that tinctures made with the mature leaves differ chemically from those made with the immature leaves, and that the greater density and dark reddish-brown colour of tinctures made with the latter description, will, in most instances, point out the kind of leaf employed, and the care bestowed in making the tincture. It may be also stated, that the quantity of extract ob-

tained from equal measures of the several tinctures varied in my experiments, but the quantity obtained from the immature leaves always exceeded that from the mature. The green colouring principle predominated in the mature leaves, and the tinctures made with them. It was also very manifest in the tinctures made by myself with the immature leaves; but in these tinctures it was modified by a large proportion of brown extract, which does not abound to the same extent in the mature leaves, and therefore the green colour of the tinctures made with the latter kind is more distinct and more permanent than the green colour of tinctures made with the immature leaves. The shades of green and brown may be accurately compared by means of bits of white blotting-paper, saturated with the tinctures respectively, and afterwards dried: and in this way minute differences may be observed by reflected light.

Tabular View of the Densities and Colours of Tincture of Digitalis, and of the Weights of Extract obtained from equal measures of eight varieties.

| Numbers of the tinctures examined. | Kind of leaves used. | Specific gravity. | Colour. | Weight in grains of extract obtained from one cubic inch of each tincture. | |
|------------------------------------|----------------------|-------------------|------------------------------------------------------------------------------------|----------------------------------------------------------------------------|-----------|
| 1. | Immature. | 0.9733 | Dark reddish-brown; no shade of green. | 13.0 | Spurious. |
| 2. | Immature. | 0.9677 | Dark reddish-brown; no shade of green. | 12.5 | Spurious. |
| 3. | Immature. | 0.9646 | Dark reddish-brown; no shade of green. | 11.8 | Spurious. |
| 4. | Probably immature. | 0.9610 | Light brown, with a very slight shade of green. | 10.0 | Spurious. |
| 5. | Immature. | 0.9583 | Lighter brown than No. 4 tincture, but otherwise nearly similar. | 10.7 | Spurious. |
| 6. | Probably mature. | 0.9406 | Brownish green. | 9.5 | Genuine. |
| 7. | Mature. | 0.9406 | Brownish green, as No. 6 tincture. | Not obtained. | Genuine. |
| 8. | Mature. | 0.9375 | Light brownish green, and more distinctly green than Nos. 6 and 7. | 9.5 | Genuine. |
| 9. | Mature. | 0.9344 | Same as No. 8. | 9.4 | Genuine. |
| 10. | Immature. | 0.9359 | When first made same as Nos. 6 and 7, but in a few days exhibited a browner shade. | Not obtained. | Spurious. |

In explanation of the results above exhibited of my experiments, it may be briefly stated, that the tinctures numbered 9 and 10 were made by myself as standards of comparison, and supposed to be of the very best quality. They were clear in a few days after being strained, and had a strong bitter taste,

and a smell peculiar to each, which, although not admitting of a description, enabled me to distinguish them from one another.

Tincture No. 9 closely resembled the three tinctures Nos. 6, 7, and 8, which were procured from three of the most respectable London druggists; and

the four tinctures, Nos. 6, 7, 8, and 9, probably possessed all the qualities of the best description of tincture.

Tinctures Nos. 1, 2, 3, 4, and 5, also closely resembled one another in their sensible qualities, but differed from the best kind of tincture in several respects; and although not entirely powerless in large doses, yet so far as a limited number of trials with them entitle me to form an opinion of their therapeutic merits, I think them much less active preparations than the tinctures Nos. 6, 7, 8, and 9. But in order to determine, with an approach to accuracy, their absolute merits as remedies under every condition, and more especially their comparative power in equivalent doses, more numerous observations of their effects on the sick are required than I have hitherto had time to make. They have, however, been commenced, and before the close of the present year will, I trust, be completed.

The Spring shoots of *digitalis*, or its immature leaves, have reappeared in the herbalists' shops, and have been purchased by the druggists, but the season has not yet arrived at which the mature leaves are gathered; and I hope the preceding remarks may have some share in removing an abuse with respect to *digitalis* which has prevailed in London for at least twenty years.

ON THE CONSTRUCTION
AND
APPLICATION OF FORCEPS FOR
EXTRACTING TEETH.

BY JOHN TOMES,
Surgeon-Dentist to King's College Hospital.

[For the Medical Gazette.]

UPON having my attention turned to the extraction of teeth, the instruments placed in my hands to effect this small yet necessary operation were—forceps for extracting the front teeth; the key instrument, for the removal of the back teeth; and the elevator, where neither of the former were effective. After using these for some time, I became dissatisfied with forceps as they are commonly made, and with the key, from the direction in which the force is applied.

To supply the place of what seemed to me defective instruments, forceps

variously shaped were constructed, and it is the business of this paper to describe these, with their proposed advantages, as compared with the instruments in general use.

It may be well however, first of all, to state what is required in instruments wherewith to extract teeth most effectively, and why the means commonly used are imperfect.

The indications in removing teeth are—First, to remove the whole of the offending tooth, or part of a tooth; secondly, to remove it with the least possible injury to the contiguous structures, as the gums and alveolar processes; thirdly, to give the patient the least possible amount of pain in the operation.

That method by which a tooth, or the remains of one, can be removed most certainly, quickly, and at the same time with the least amount of injury to the adjoining parts, will also remove it with the least pain.

To fulfil these indications, recourse must be had to an instrument so formed that it shall grasp the tooth alone, and by the required force applied nearly in the axis of the tooth, remove it. Such instruments are forceps; but forceps so constructed that they shall accurately fit the tooth to be extracted, and so fashioned at the jaws, nibs, or blades, that they shall readily separate the gum from the neck of the tooth, to which point they shall arrive by simply placing the extremities of the jaws at the edge of the gum, closing the handles, and at the same time pressing the instrument steadily in the direction of the tooth, till it comes in contact with the free edge of the alveolar process. As the teeth are variously shaped, so will it be necessary to have forceps of different forms; in fact, a pair fitted to each kind of tooth. By forceps so constructed most teeth may be removed in less time than by any other tooth-extracting instrument at present in use; also with less pain to the patient, and without inflicting any farther injury to the gums and alveolar processes than must necessarily result from the forcible separation of a tooth from its natural attachments.

An instrument which in its employment requires that force should be applied to the contiguous parts as well as to the tooth to be extracted, is an imperfect instrument for the required pur-

pose; or an instrument which, by its form and mode of application, requires that greater force should be used than would be necessary for the dislodgment of the tooth, supposing that force to be applied in the most advantageous direction, is also an imperfect instrument, and but ill fitted for the purpose for which it was designed. Such, however, are the imperfections of an instrument in very general use for the extraction of teeth—the “key:” in the application of which the fulcrum is rested on the alveolar process, between which and the fulcrum the interposed gum is subjected to considerable pressure; just as much, indeed, as may be necessary for the dislocation of the tooth. By this treatment the gum is often considerably bruised, sometimes so much so as to lead to suppuration of the injured part, and always to an unpleasant degree of soreness. The force used in extracting a tooth with the key must be much greater than the actual force required to effect the operation, because the power is applied in a lateral direction, a direction in which the tooth offers great resistance, especially in molares of the lower jaw, where the lateral alveoli are strong, and composed of dense bone.

I am quite aware that there are many and eminent surgeon-dentists who use and speak very highly of the *key* instrument; and no doubt it is very much to be preferred to the forceps ordinarily kept by surgical instrument makers: forceps which are applicable to no one tooth in particular, when applied touch only at two or three points, and are quite incapable of being passed down to the neck of the tooth, unless the gum be previously cut away, and even then very imperfectly. Forceps for extracting the molares of the upper and lower jaws are commonly kept for sale: the jaws of these are simply curved at their extremities, and each jaw alike, so that one instrument is equally applicable to molares of either side of the mouth, whether right or left. In many instances teeth may be removed by such means, but if the destined tooth be much decayed, the operation will be difficult and uncertain in its results; and whatever state the tooth may be in, there is great risk of its being crushed, from the circumstance of the pressure made through the instrument not being

diffused over a large surface of the circumference of the tooth, but confined to two or three points. It is no wonder that such instruments should fall into comparative disuse, and be spoken of as suited only to break off sound teeth, or to extract loose ones. These observations apply principally to forceps for extracting the bicuspides and molares. The incisores are generally, though not always, removed with forceps, or with the elevator. The wisdom teeth are sometimes removed by the latter instrument.

Mr. Bell recommends for the removal of the bicuspides and the anterior molares of the lower jaw, the use of the *hawk's-bill* forceps: this instrument, when well made, must be considered as amongst the best of forceps. For my own use, however, I prefer those that have straight blades or jaws, with the curve, if any be necessary, in the handles.

Dr. Flagg, of Boston, has contrived forceps for the extraction of every kind of tooth. I have not been able to obtain any of his instruments, but, from the description and plates given of them in Fitch's “System of Dental Surgery,” I believe they are unlike those I have myself devised.

A work entitled “Operations on the Teeth,” by Mr. Snell, contains a description, with plates, of a form of forceps used by the author for the extraction of the molares. The principal aim of the inventor was to have two points of metal coming out from the edge of each jaw of the instrument; the object of these points being to be passed between the fangs of the teeth. These forceps admit of but very limited use, as the fangs of the molares, especially the second and third, are liable to be agglutinated; which condition, in each particular instance, is known only after the tooth has been extracted: but besides this, it is a matter of some difficulty, in any case, to get these two points between the fangs; neither is the attempt unattended with suffering to the patient.

Forceps for extracting the anterior teeth are to be found every where, though I have not yet met with any but such as were so clumsily constructed, that to remove the stump of an incisor with them would be difficult indeed. Neither will the so-called “Sheppard's safety forceps” be an exception to this

observation. What forceps Mr. Sheppard might have had himself I do not know; but those sold as his are next to useless: for although the principle upon which they are proposed to be made is a correct one, yet it is not carried out in the formation of the instruments.

Different shaped teeth requiring forceps shaped to them, it will be necessary to describe partially the teeth, and then the forceps individually, that the peculiar shape of each instrument may be understood. Before doing so, however, I should state that it is quite impossible for any person to extract teeth properly, whatever instrument may be used, especially if the forceps be chosen, unless the operator is perfectly acquainted with the form of each tooth, with the relative position and size of the fangs, with their direction in the alveoli, with the general form of the alveoli themselves, and the positions at which they offer the greatest and the least resistance.

I am not prepared to say that the forms of forceps which I am about to describe are possessed by myself alone, or by those who have chosen to take mine as a copy. Other practitioners, feeling the want of such, may have been led to construct similar instruments. They have not, however, to the best of my knowledge, described them; neither, as far as I can learn, are their patterns in the possession of any surgical instrument maker. Of this I am certain, that the vast majority of the practitioners who extract teeth neither have knowledge or possession of similar instruments. I therefore offer no apology for printing an account of tooth-forceps which, to my view, seem much superior to those commonly employed. Medical men, engaged in general, and especially parochial practice, are very frequently called upon to extract teeth, and by them the operation, for want of better instruments, is generally performed with the key; and not, in all instances, with the most favourable results. I have seen many cases of sloughing of the gums; and now and then exfoliation of the alveolar process. I do not mean to argue that these are the common results of using the key, but they are not very unfrequent consequences when the instrument is in the hands of an unpractised operator.

With well-made forceps no such acci-

dent can occur, if ordinary care be taken; and it is more easy to learn to use forceps with good effect than the key. I believe it requires more practice and care to use the key to good purpose, than any other instrument used to extract teeth; yet, when in the hands of a skilful operator, it is no doubt a useful instrument, and as such should not be neglected, since cases may occur in which it would be of value; though I believe such cases to be rare.

After stating some general conditions which I think inseparable from good forceps, whatever may be their particular form, I will describe those that have been planned or modified by myself; and I do so without wishing to claim any merit as an inventor, but merely as having carried out a principle admitting of general application, which has been neglected, or at least neglected to have been made public.

All forceps whatever should embrace the tooth they are used to extract at its neck; the neck being that part which is between the termination of the enamel and the free edge of the alveoli, and which is covered by gum. In order to arrive at this part of the tooth without difficulty, or unnecessary pain to the patient, the jaws must present an inclined plane, terminating in an edge. The external surface of the jaws of forceps, when closed, should present something like a cone, or parts of several cones, with the apex or apices cut off; and a perpendicular section should present an inclined plane, terminating in an edge, but more or less curved, as may be suitable to the particular instrument. The length from the joint to the edge of the jaws should on no account be greater than will be necessary to allow sufficient space for the reception of the crown and neck of the tooth, so that no strength may be lost.

The fangs of all teeth having a general conical form, forceps, when well made and applied, should be but as a lengthening of the cone towards its base. For removing teeth which are not decayed down to the gums, the ends of the jaws should be square; but when nothing but the fang remains of a tooth, rounded ends are the more convenient, as with that shape they are readily introduced between the fang and inclosing alveolus. Instruments

for extracting stumps should be made altogether lighter, the jaws thin and sharp at their convex ends, so that they may be made to cut rather than tear the membrane connecting the fang with the adjoining tissues.

Forceps should be constructed and used upon the principle of lengthening the tooth for the extraction of which they are intended; thus enabling the operator to move it from side to side, or rotate it if the fang be single, and of a shape admitting of such motion.

After these lateral movements have been produced, the tooth may, unless the fangs have some peculiar position or shape, be raised in a perpendicular direction, leaving as little injury from its removal as the operation can admit.

Forceps for the extraction of the incisores, cuspidati, and bicuspidés.

A section through the neck of an incisor of the upper jaw will show that the anterior is larger, and forms part of a greater circle, than the posterior surface. Now the end to be attained in the application of forceps is to apply them over as large a surface as possible, thereby avoiding the chance of fracturing the tooth by the pressure of the instrument. To extract these teeth, therefore, the jaw to be applied to the posterior surface must have a smaller curve than that for the anterior. An average tooth, in this as well as in other cases, when new instruments are required, should be selected and given to the forceps-maker, and he should be instructed to make the jaws to fit the neck of the tooth exactly, leaving sufficient room for the crown of the tooth to be free from pressure, but not more than will be necessary to clear the enamel. When the forceps are closed upon the tooth they should embrace not only the anterior and posterior, but a part of the lateral surface also. The lateral incisores require forceps made upon the same principles, but somewhat less in size. These are liable to greater variation in external dimensions than any other teeth. Sometimes they are very small indeed, at other times they are almost as large as the neighbouring teeth. It will be advantageous therefore to have different sizes of instruments from which to select.

The incisores of the lower are smaller than those of the upper maxilla, and much more compressed laterally. For-
